Birds, as everyone knows, periodically renew their feathers, some oftener than others ; but all, or nearly all, probably at least once a year. As a rule—though often when undergoing the change they mope and show otherwise signs of the need of a tonic—the moult is effected without seriously incapacitating them. Geese and most kinds of ducks are an exception, and, at least in the case of the males, for a time commonly completely lose the power of flight. Why this should be so, science has never yet been able to suggest. But it is, incidentally, where the birds most congregate, of immense advantage to human beings. It is during the moult that the Samoyedes, without much more exertion than is involved in driving sheep into a pen, lay in their most important winter stores.

The most interesting chapters in Mr. Trevor Battye's "Icebound in Kolguev" are those in which he describes the great autumn goose drives in which he took part, when the birds, unapproachable at any other time, were knocked on the head by thousands to be salted down for future consumption.

Nature has been a little more pitiful to the ducks than to the geese, and for their protection has arranged that, during the week or two that the duck is practically flightless, he shall doff his conspicuous colouring, and masquerade in the unobtrusive dress of the female. In the case of the mallard, the colour even of the legs and beak is changed.

Nature in most of her processes works economically. In the matter of the drake's "eclipse" she is reckless. The strain put on the bird's system, for no other apparent reason than to avoid startling contrasts and produce the desired results gradually, is almost incredible.

Two-thirds of the mallard's feathers (viz. those of the head, neck, breast and parts of the back and scapulars),

writes Mr. Millais, as the results of close observation, "between June 15 and October 10, undergo *a double moult*, that is to say, the feathers are actually shed twice, whilst one-third (viz. the long scapulars, wings, tail and back feathers) are renewed only once, and during all the time, both in the shedding of the old feathers and the assumption of the new, there is a process of constant sympathetic change of colour."

Mr. Millais has something even more strange to tell.

"I am convinced," he writes, "that a bird has full power to command the moult as it will, and also"—stranger still—"to infuse or withhold colouring matter as it thinks necessary."

The Lord of creation "cannot make one hair black or white."

His conclusions, startling as they may be, are those of a thoughtful and observant man who has conscientiously devoted many years to a close study of a fascinating subject.

It is not, as a rule, until the drake has completely assumed the duck's brown dress, harmonising as it does with the colour of the dying reeds, that the quills are shed. The operation is got through without an hour's waste of time. "I have known them" (Mr. Millais must speak for himself again) "all come out together in one day, the new flush starting at once."

The duck has others to think of besides herself. If she, like her mate, were to be deprived of flight-power, it would often be at the risk of her brood, and so her wing feathers are shed, like those of most birds, gradually, and she seldom, if ever, quite loses the use of her wings. If she has a second brood to look after, and is thus occupied later than usual with family cares, even this comparatively harmless wing moult is postponed for a more convenient season—as Mr. Millais believes, if we read him rightly—by a direct action of will on her part.

It is a wonderful story, but nothing in Nature is incredible merely because incomprehensible.

Mr. Millais has a very simple answer to a question which has puzzled many others than scientific naturalists. When ducks and other birds which usually nest on the ground change their habits, as they often do, and lay in trees, how do the young ones—*nidifugae* who leave the nest as soon as they are hatched—manage to get down?

At the mother's call, he says, they throw themselves down and alight unhurt. The explanation is good so far as it goes, and may, not improbably, be in most cases true. But it would be rash to accept it as of universal application.

Three young birds found dead at the foot of a tree in a park in Sussex led this spring to the discovery of a moorhen's nest at a very considerable height from the ground. The young birds were all well nourished and had been apparently killed by the fall.

Woodcocks have been more than once seen by trustworthy witnesses in the act of carrying their young, and there is no reason to suppose that ducks and other birds cannot on occasion as easily do the same.

There are many other directions in which, if space permitted, it would be pleasant to follow Mr. Millais's lead. But enough has, perhaps, been said already to show that his book is original and very interesting. The pictures are all excellent. Among the most interesting is the pencil sketch by the author, facing p. 60, of the beak of a shoveller, with its strange spoonbill tip and the hanging bristles, in which—as in a sieve, or in the great mouth-fringes of the whalebone whale, to compare small things with large—dainty morsels are trapped as the bird skims the water as he paddles about with extended neck.

"Here" (the quotation is from the note attached to the sketch) "we see a wonderful provision of Nature. The comb-like teeth or *laminae* of the surface-feeding ducks are developed in proportion to the extent to which the particular species feed on the surface or otherwise. An omnivorous and somewhat coarse feeder like the mallard only possesses them in a very rudimentary form, whereas the shoveller, which is constantly skimming the surface for fine substances, has them greatly developed in both upper and lower mandibles."

Mr. Thorburn contributes eight full-sized coloured plates. He is still, among English bird-artists, an easy first. But in some of his pictures, notably Plates xxx. and xxxvii., garganeys chasing water-beetles, and the pintails, Mr. Millais has run him close.

The only fault to be found with a beautiful book is that in choosing his subjects for illustration the author has, perhaps, ridden his hobby "Eclipse" a little too hard.

The best work, excepting in the case of the few rare visitors figured, which are, strictly speaking, scarcely British, is confined almost entirely to birds in immature or transitional plumage. In a book of natural history, destined to take a well-earned place for some years to come as the standard work on our surface-feeding ducks, a few plates might with advantage have been spared, if only as a sop to unscientific bird-lovers, for ducks and drakes at their best. T. DIGBY PIGOTT.

A FRENCH TEXT-BOOK OF ZOOLOGY.

Traité de Zoologie Concrète. Par Yves Delage et Edgard Hérouard. Tome ii., 2[me] Partie, Les Cœlentérés. Pp. x + 848. (Paris: Libraire C. Reinwald, 1901.)

THE volumes of the "Traité de Zoologie Concrète" already published are so well known and have been so acceptable to zoologists that the present volume, dealing with the Cœlenterata, scarcely requires any recommendation. While it leaves little to be desired in such important matters as abundance and excellence of illustrations, bibliography, index and glossary, the chief merit of the "Traité de Zoologie Concrète" must be attributed to the logical and systematic method of exposition adopted by its authors. The majority of zoological text-books, following the German model, give a brief and insufficient definition of each class or order of the animal kingdom, and this is succeeded by a discussion of the organology and embryology of the class or order that is generally so diffuse as to leave the student in a state of hopeless uncertainty as to what are the characteristic structural features of the group in question. Recognising the importance of fixing clear and definite ideas of structural relations in the student's mind, MM. Yves Delage and Hérouard have adopted the time-honoured plan of illustrating the anatomy of each important group of animals by a description of a morphological type, which

serves as a standard to which all the other members of the group may be referred. The method is familiar enough, but has fallen into discredit because previous authors have made too little use of it and have confined themselves to the description of one or two animals as examples of a large class, whence it has resulted that students have too frequently formed narrow conceptions of animal structure and have underestimated the wide range of variation of which animals belonging to the same class are capable. The "Traité de Zoologie Concrète" has the merit of having avoided this error by describing a morphological type, not only for each class or subclass, but also for each order, suborder, and even for each tribe. Thus a general description is given of the morphological type of the order Octanthida (Alcyonaria); Kophobelemnon is taken as a type of the suborder Pennatulidæ; Renilla, Umbellula, Kophobelemnon, Pennatula and Gœndul are taken as the morphological types of the five tribes into which the Pennatulidæ are divided, and a sufficient description of the families and genera included in the tribe follows the description of each type. This system is consistently adopted throughout the work, and as the types are illustrated by well-designed schematic drawings, the essential characters of all the subgroups are brought in the clearest possible manner before the mind.

The book gives evidence of a minute acquaintance with zoological literature, and the numerous illustrations are largely copied from treatises of a recent date. In the latter respect, the volume on the Cœlenterata is considerably in advance of other text-books, for it is only too frequently the case that old and sometimes obsolete illustrations are copied from book to book, while more recent work is ignored.

The classification adopted does not depart widely from accepted lines. The Cœlenterata are divided into two branches, Cnidarea and Ctenarea, the latter being co-extensive with the Ctenophora. Though some authors would separate the Ctenophora from the Cœlenterata on the ground that they have an embryonic mesoblast, MM. Delage and Hérouard give sufficient reasons for retaining them in the phylum in which they have so long been classed.

The Cnidarea are divided into two classes, Hydrozoaria and Scyphozoaria, the former including all the forms usually classed under Hydrozoa, except the Scyphozoa, which have been placed along with the Anthozoa in the class Scyphozoaria. The union of these two groups is a step in advance, abundantly justified by recent anatomical and embryological researches. In the class Hydrozoa it is noticeable that the Siphonophora are raised to the rank of a subclass, the other subclass, Hydrophora, including the Hydridæ, the Hydromedusæ, the Trachymedusæ and Narcomedusæ. The grounds for this distinction are probably sufficient, but it is open to question whether the classification of the Siphonophora adopted in this work is an improvement on that of Hæckel, and one cannot but regret that the authors' love of symmetry or their anxiety to satisfy the claims of priority should have led them to abandon well-known and generally accepted names for others which are unfamiliar. For example, the order Chondrophorida sounds strange to most ears; the name is due to Chamisso, but has never come into general use, and that of Disconectæ is preferable because better known. Again, in the Scyphozoaria the name Octanthidæ, derived from the Octactinia of Ehrenberg, is preferred to Alcyonaria, though the latter is in general use and there is no good reason for abandoning it. The name Actinanthidæ, again, is substituted for Zoantharia, without sufficient reason, and the classification of the order is open to many objections. It scarcely seems consistent to class Edwardsia and Tealia under the Hexactinidæ, though the authors justify the inclusion of the former genus because of Faurot's discovery of micromesenteries completing the first cycle of six pairs in certain species. The division of madreporarian corals into Hexacorallidæ and Tetracorallidæ is quite unjustifiable in the present state of our knowledge, and in spite of their sharp criticism of Miss Ogilvie's work on the microscopic characters of the corallum (p. 602), the authors might have given her the credit of having demonstrated the unity of structure in recent and so-called rugose or tetracorallid corals. Indeed, they are open to the charge of inconsistency in this respect, for they have borrowed largely from her figures and adopted her possibly erroneous views on the mode of formation of the corallum, but have refused to accept some of her most important and well-grounded conclusions. It is scarcely possible, at the present time, to retain the groups Aporina and Porina (Aporosa and Perforata of Milne-Edwards), though it must be confessed that no acceptable alternative has been offered, and MM. Delage and Hérouard, while retaining a discredited classification, give a very good summary of the various schemes that have been proposed by different authors.

Knowing the previous writings of M. Delage, one is not surprised to find that, in discussing the origin of atolls and barrier-reefs, he takes the opportunity of making a double attack on the Darwinian theories of the formation of coral reefs and natural selection. It is to be regretted that he allows himself to write so dogmatically on these subjects, for it is by no means the case that the theory of natural selection has been abandoned by zoologists in general as a "hypothèse séduisante," attractive but inadmissible. He would seem to have overlooked the school of statistical zoologists, whose work, so far as it has gone, has done much to strengthen the opinion that natural selection is by far the most potent factor in the evolution of species. Finally, when the complete results of the boring at Funafuti are published, M. Delage will probably be obliged to admit that the great English naturalist was not far wrong also in his speculations on the origin of atolls and barrier reefs.

G. C. BOURNE.

WAVES AND SOUND.

Wellenlehre und Schall. Von W. C. L. van Schaik. Translated into German by Dr. Hugo Fenkner. Pp. xi+358. (Brunswick: F. Vieweg and Sohn, 1902.) Price Mk. 8.

NO portion of physics is more difficult to treat in an elementary way than that of sound; the consequence is that though advanced treatises of magnificent quality exist, an elementary text-book in English which

is less severe than these, but which is something more than a mere description of acoustic phenomena, is still a desideratum. Where attempts have been made to supply the want the result is not successful, owing chiefly to the clumsy methods employed in "getting round" the calculus. We are not upholders of the doctrine that the calculus should be "got round"; it is much better, we think, to "get through" it. Experience in teaching others has taught us that pupils find no difficulty in grasping its elements, and this is the case whether they are taught analytically or geometrically. Why then should we seek to devise elaborate methods of eluding the calculus—methods which in most cases we would never think of employing ourselves, and which, moreover, are usually only adapted to the particular problem for which they are devised—when a straightforward introduction to the methods we use ourselves would clear the ground and render the student's progress easy, and enable him the sooner to be his own path-finder instead of needing to rely on the guidance of others?

The book under review cannot supply this want in England, for it is a translation into German (from the Dutch); the substance of the book is in the above respect, however, entirely to our mind.

No calculus is employed in name; but the notion of it is everywhere. Velocity is the limiting value of a ratio and so is acceleration, and their values are found by the usual direct methods employed in proving the initial theorems of the calculus. We would have gone a step further and given the process a name, in order to suggest to the student to what branch of mathematics these and similar theorems belong. But the notion is the main thing. There is nothing here which a man will discard at a future time, having learnt a better way; though he will, of course, learn to abbreviate the logical statements of the process into the mere symbols dx/dt and d^2x/dt^2.

Without making a full analysis, the following subjects dealt with may be briefly stated:—In the mathematical treatment: simple harmonic motion—waves and their composition, with a proof of all the simple theorems.

Fourier's theorem is given, but not proved; it is illustrated, however. The dynamical equation to simple harmonic motion is given, and the motion deduced by showing that it satisfies the equation. Even the case of a restoring force involving second as well as first power of displacement is given, on account of its importance in connection with the Helmholtz theory of the production of combination tones. The equation to damped motion is treated as an article for faith; its properties, however, are lucidly described.

Although the experimental phenomena are mainly collected together, the mathematical portion is not wholly free from experimental illustration. For example, we specially note a device which should be found useful for illustrating the behaviour of forced oscillations with different degrees of damping.

Perhaps the most interesting section is that dealing with the interference and diffraction of waves. This might be amplified by an account of recent experiments imitative of Lloyd's mirror and diffraction from two apertures (Young's experiment); and, in particular, an account of Rayleigh's brilliant application of the principles of diffraction in *restricting* the spreading of sound to one plane by suitably shaping the aperture of the fog horns employed in coast signals would form an excellent additional illustration.

The last chapter is concerned with movements of air in pipes, concluding with an account of the secondary motions usually developed, such as the small striations in the cork figures in a Kundt's tube, which were investigated by Walther König and others (König is mentioned without being discriminated from R. König). These are highly interesting, though many will no doubt consider them rather out of place in an elementary book.

There is no mention of Rücker's important experiments in connection with combination tones.

OUR BOOK SHELF.

Malarial Fever, its Cause, Prevention and Treatment. Containing full Details for the use of Travellers, Sportsmen, Soldiers, and Residents in Malarious Places. By Ronald Ross, F.R.S., Walter Myers Lecturer in the Liverpool School of Tropical Medicine. Ninth edition, revised and enlarged. Pp. 68. (London: Published for the University Press of Liverpool by Longmans, Green and Co., 1902.) Price 2*s*. 6*d*.

THIS little book is an enlargement of a previous work by the same author, and should prove of the utmost use to those for whom it is written. The exact knowledge concerning the epidemiology of malaria which has been attained during the last six or seven years has made clear the principles upon which the disease may be prevented in the individual and perhaps exterminated in the locality. The wide dissemination of these principles and of the facts upon which they are based is the next obvious step in the campaign against malaria, and the Liverpool School of Tropical Medicine has done good service in the publication of this work. Within the short compass of some seventy pages we find a lucid and succinct account of the nature and life-history of the malarial parasite, of the habits and life-histories of the gnats which serve as its definitive hosts, of the precautions to be taken to avoid infection, and of the elementary treatment of the disease should it be acquired. In short, nothing is wanting that should enable an intelligent man, even if devoid of any scientific training, to escape malaria, even where it is most virulently endemic. The writer's wide experience, and the important share which he has taken in building up our knowledge of the disease and its propagation, are a sufficient guarantee of the accuracy of his information and of the practical value of his rules for guidance. There is a consensus of practical experience that, by attention to the rules here set forth, a man may safely pass through countries where malaria of the most dangerous type prevails. We recommend the book heartily to all who have occasion to sojourn in such lands.

Velocity Diagrams. Their Construction and Uses. Intended for all who are interested in Mechanical Movements. By Prof. C. W. MacCond, A.M., Sc.D. Pp. iii + 116; 83 figures. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1902.) Price 1.50 dollars.

IN this book some examples of plane motions of machines are worked out. The title well describes the scope and contents of the work and the very modest aims of the author.

The main problem to which the discussion is directed is:—Given a skeleton drawing of a mechanism and the speed of the driving point, to find graphically the corresponding speed of the driven point, and to show the latter all throughout the cycle by means of a rectangular

curve of speed plotted on a time base. The author believes that this curve exhibits the kinematic action of the machine more clearly and directly than any other form of diagram.

Beginning with the composition and resolution of velocities, it is shown how the constraints of slides, pivots and rigidly connected points affect the ordinary rules for vectors, and one or two simple special rules are established. These are applied systematically to selected mechanisms such as pruning shears, quick return motions, direct-acting and oscillating cylinder engines, epicyclic trains of wheels, the pilgrim-step motion, &c., until the reader becomes quite familiar with the process.

No attempt is made to give more than a cursory and very limited account of the plane motions of mechanisms, consequently many important theorems and constructions of a general nature find no place. Simple harmonic motions, and harmonic analysis, often so useful, are not considered. Acceleration is only incidentally referred to in showing how an acceleration-time curve can be determined graphically from a velocity-time curve. The author has evidently imposed severe restrictions as to the amount of ground to be covered. But so far as the subject is dealt with, the methods and demonstrations are very clear and convincing, and the diagrams are well drawn and beautifully printed.

Spiderland. By Rose Haig Thomas. Pp. viii + 227. (London: Grant Richards, 1902.) Price 5*s*.

THIS is a charming little book, based on the authoress's original observations on a variety of animals and plants, and cast into a poetic form likely to interest children in natural history. It is dedicated as follows:—"To my Son, whose wondering child-eyes first taught me to look deeper into the workings of Nature, and to all the Children I know and shall never know, I dedicate these simple tales." As we remarked when reviewing elsewhere the first edition, printed for the author in 1898, which comprised only the first twelve tales, whereas twelve more are added in the present edition, the book reminds us of the "Episodes of Insect Life," on the one hand, and Mrs. Gatty's "Parables from Nature" on the other. The mode of treatment resembles that of the former book, and the general style the latter. A great variety of subjects are dealt with, and only one or two of the stories relate to spiders; among others, we note such titles as "The Tree Frogs," "Pistil the Peace-maker" (a more elegant setting of the old fable of the "Stomach and the Limbs"); "Thomisa Citrina, the Robber-Mother"; "The Wedding of the Fly Ophrys"; "The Green Caterpillar" (a study somewhat resembling one of Mrs. Gatty's, but dealing with a more mournful phase of caterpillar life, an ichneumoned caterpillar); "Hymen, the Worker Ant"; "Nimble Nat, the Gay Grasshopper"; "Cocky: a London Love-Tale" (sparrows); "The Romance of the Water Beetle"; "The Lemming," &c. The remarks on the lemming are interesting, and will be new to many readers. Here and there we meet with a trifling oversight; the authoress has travelled in France and Norway, and has forgotten to note that processionary caterpillars are not British; and the auditory organs (hardly "ears") of grasshoppers are situated, not in the hind legs, but in the front legs.

Children are easily interested in natural history and insect life; and a poetical view of some of its phases, such as Mrs. Thomas has here given, is likely to prove more attractive to them than a purely didactic book, like "Uncle Philip's Conversations with Children," which was almost the first book on natural history read to the present writer in his childhood. Naturally, the stories written by Mrs. Thomas are not all of equal merit; but most of them are excellent, and we regret that our space will not allow us to give a sufficiently long quotation to afford a fair idea of the style of her book. W. F. K.

Tuberculosis as a Disease of the Masses, and How to Combat It. By S. A. Knopf, M.D., of New York. Adapted for English use by J. M. Barbour, M.D. Pp. 76; 25 figures. (London: Rebman, Ltd., 1902.) Price 1*s*. net.

IN plain, simple language, devoid of technicalities, Dr. Knopf presents an accurate account of the causes of tuberculosis, some details of the symptoms of a few of its many phases, and indicates the chief hygienic principles which underlie the present-day methods of treatment.

He emphasises the fact that tuberculosis is a contagious and therefore a preventable disease, that the child of a tuberculous mother is not itself necessarily tuberculous, although it frequently acquires the disease—the maternal kisses often being the channel of infection—that man may derive the infection from animals and that he may in turn transmit the disease to them, and above all that *tuberculosis is a curable disease.*

The author fully explains the duty of the consumptive to himself and to his fellows, and points out in no uncertain manner the real danger attendant upon the habit of spitting elsewhere than in a proper receptacle by the subjects of this disease. He also gives much excellent and useful advice with regard to the practice of calisthenics by, and the inculcation of habits of cleanliness in, the young, and the value of fresh air and sunshine as factors in the prevention and cure of tuberculosis, as well as many suggestive hints on the home care of consumptives.

We are not surprised to learn that this essay was awarded the first prize (200*l*.) offered by the "International Congress for the Study of the Best Way to Combat Tuberculosis as a Disease of the Masses," which met at Berlin, and that it has already been published in five languages besides English. It is an excellent treatise, and should be in the hands of every individual, sick or well, who has at heart the physical welfare of his fellow mortals.

The Teacher's Manual of Object Lessons in Geography. By Vincent T. Murché. Pp. xvi + 334. (London: Macmillan and Co., Ltd.) Price 3*s*. 6*d*.

HOW great has been the improvement in methods of teaching during recent years can be measured to some extent by a comparison of newly published books intended for use in public elementary schools with those in circulation twenty years ago. The old implicit reliance on the child's faculty for memorising is fortunately giving place to an appeal to his observation and incipient reasoning powers. Mr. Murché's latest addition to his already extensive series of books on elementary science is marked by his usual clearness of exposition and by that helpfulness for which he is justly highly esteemed by teachers in elementary schools. But the bewildering miscellany of type, with its frequent transitions from Roman to italics and from these to Clarendon and capitals, makes the volume a trying one to read and raises the question of the possibility of such over-emphasis defeating the object in view. It is unfortunate that in explaining volcanic activity the author speaks of "dense volumes of flame and smoke" which "burst out from the crater," and that he instructs the teacher to explain "that ages ago this earth on which we live was a burning mass like the sun." This seems to indicate a want of clearness as to the nature of smoke and burning; it will certainly give the child a wrong idea. But the book should do a great deal to improve the teaching of geography.

William Gilbert of Colchester: a Sketch of his Magnetic Philosophy. By Charles E. Benham. Pp. 96. (Colchester: Benham and Co., 1902.) Price 2*s*. net.

THE immediate occasion of the appearance of this little book is the issue to the subscribers of the Gilbert Club of the English translation of "De Magnete." The author

has attempted, and with real success, to show what manner of man Gilbert was, wherein lay his genius, what were his merits, and what also were his faults and failings. Mr. Benham dwells on the circumstance that, although Gilbert's actual discoveries were few and crude, he must be judged rather by the spirit of his work. "He was not the builder of sciences, but the architect of a truly scientific spirit; and his life-work consisted in the doctrine, new to England, that all scientific knowledge must be founded on practical experiment and observation alone, instead of upon speculations and theories evolved out of inner consciousness." The successive chapters of the book deal with the old magnetic philosophies, magnetic motions and electric force, the magnet's "directive virtue," the variation of the compass, the dip and "orbes of virtue" of the magnet, the life of the Universe (in which Gilbert, although no Manichean, was clearly a believer) and the Copernican theory. The author is particularly happy in his treatment of this last topic; but throughout the analysis of Gilbert's work is accurate and discriminating. The book is illustrated with a picture of Gilbert's terrella, and another of his tombstone in the church of Holy Trinity, Colchester. S. P. T.

The Vocal System based on the Fundamental Laws of Language. By G. Lionel Wright. Pp. 20. (Published by the Author, Upper Belgrave Road, Clifton, Bristol.) Price 1*s*. net.

IT is now recognised that teaching to read is not the simple matter which it was once thought to be. In recent years one system has followed another in rapid succession, and each has claimed in turn that by its introduction the time taken by the child to learn to read the mother tongue was much reduced. There seems to be a chance that these experiments may eventually reduce the difficulty of this first step in human education to a minimum. Mr. Wright proposes to make extensive use of the blackboard and of *vivâ voce* methods of instruction, and to start teaching the child to read by making him learn the five vowels. When this has been accomplished, the learner is introduced, by carefully graduated steps, to certain combinations of vowels and consonants, which are clearly indicated in this brochure, and by following which Mr. Wright claims that children may read at the age of six. A somewhat minute examination of the contents of the pamphlet leads us to think that Mr. Wright would be well advised in making his instructions to the teacher much more detailed and explicit if he is anxious that his system should become widely adopted, for at present the teacher will be, at several points, at a loss to know the next step in the course of work.

The Lake Counties. By W. G. Collingwood. (Dent's County Guides.) Pp. xii + 392; illustrated. (London: J. M. Dent and Co.) Price 4*s*. 6*d*. net.

THIS little volume—the fourth of the series to which it belongs—will be found invaluable to all who visit the Lake District. In addition to being an excellent guide, with a number of itineraries and many maps, it contains four chapters on the natural history of the district, the birds being described by Miss Armitt, the butterflies and moths by Canon Crewdson, the flora by Mr. S. L. Petty, and the geology by Prof. Hull. In the chapters on fox-hunting, angling and shooting, the sportsman will find abundant matter for interest, according to his particular taste. This volume fully maintains the high reputation of its predecessors, and is, in fact, all that a guide should be. Those tourists who wish to go more deeply into the natural history of one of the most interesting and beautiful districts in England will find all they want in the more pretentious volume by the late Mr. Macpherson entitled "Lakeland." R. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Symbol for Partial Differentiation.

PROF. PERRY'S difficulty (NATURE, May 15, p. 53) is without doubt a real one, and is deserving of serious consideration. In connection therewith the following extract from a paper at present passing through the press may be found interesting, at least on the historical side. It is in reference to a memoir of Jacobi's published in the year 1841 in the twenty-second volume of *Crelle's Journal*:—

"The subject of the notation of differential-quotients is then entered on at some length (pp. 320-323), and the decision made to use ∂ in the manner which soon afterwards came to be familiar. The insufficiency of this notation is not forgotten, however, although its advantages over the different devices of Euler and Lagrange are recognised, his illustrative example being the case of $\partial z/\partial x$ where z is a function of x and u, and u is a function of x and y. He puts the whole matter in a nutshell when he says that it is not enough to specify the function to be operated on and the particular independent variable with respect to which the differentiation is to be performed, but that it is equally necessary to indicate the involved quantities which are to be viewed as constants during the operation."

To this the following footnote is added:—

"I may state in passing that in 1869 when lecturing on the subject I found it very useful to write

$$\phi\overline{x,\ y,\ z}\ ,\quad f\overline{s,\ t,\ u,\ v}\ ,\quad \ldots\ .$$

in place of

$$\phi(x, y, z)\ ,\quad f(s, t, u, v)\ ,\quad \ldots\ .$$

and then indicate the number of times the function had to be differentiated with respect to any one of the variables by writing that number on the opposite side of the vinculum from the said variable; thus

$$\phi\overset{1\quad 3\quad 2}{\overline{x,\ y,\ z}}$$

meant the result of differentiating once with respect to x, thrice with respect to y, and twice with respect to z.

"Using this notation to illustrate Jacobi's example, we see that if it were given that

$$z = \phi\overline{x,\ u}$$

we should have

$$\partial z/\partial x = \phi\overset{1\qquad}{\overline{x,\ u}}\ ;$$

but that if it were given that

$$z = \phi x,\ \overline{u} \quad \text{and} \quad u = \psi\overline{x,\ y}$$

then we should not be certain as to the meaning of $\partial z/\partial x$, as it would stand for

$$\phi\overset{1\qquad}{\overline{x,\ u}} \text{ or } \phi\overset{1\qquad}{\overline{x,\ u}} + \phi x,\overset{1}{\overline{u}}\ .\ \psi\overset{1\qquad}{\overline{x,\ y}}$$

according as u or y was to be considered constant."

Cape Town, S.A., June 5. THOMAS MUIR.

I AM glad to think that a pure mathematician sees the difficulty met with by users of mathematics. I wish that men who write to me privately would publish their remarks. One correspondent says: "I think 'the mathematicians' made a rather stupid blunder when they introduced ∂ for partial differentiation. This way: nearly all differential coefficients *are* partial; even a complete one (assumed complete) may become partial by extension of the field of operation. So an old investigation of Kelvin's, for example, using d throughout, is, by 'the mathematicians,' replaced by the same using ∂ throughout, except one or two here and there! What is the use? It gives a lot of trouble, and as printers haven't always ∂'s, or proper sized ∂'s, it makes bad work. It should have been ∂ itself that was introduced for the exceptional use, thus making next to no alteration in the classical investigations." These are, indeed, my own views, but as my pupils go forward to University examinations I

advise them to adopt the fashion which is likely to please the examiners.

In thermodynamics we cannot easily adopt Mr. Muir's suggestion. Take the simplest case of unit quantity of mere fluid. v, p, t, E and ϕ are such that they are all known if any two (except in certain cases) are known. Any one *may* be expressed as a function of any other two. My symbol $\left(\frac{dE}{dv}\right)_p$ is quite definite. But to adopt Mr. Muir's suggestion I must say:—

Let $E = f\overline{v,\ p}$ then $f^1\overline{v,\ p}$ is what my symbol means. Inasmuch as my letters stand for the same quantities irrespective of the letters of which they are functions, I use one letter E where on Mr. Muir's suggestion I must use E as $f\overline{v, p}$ or $F\overline{v,\ t}$ or $\psi\overline{v,\ \phi}$ or $\chi\overline{p, t}$ or $\theta\overline{p,\ \phi}$ or $\xi\overline{t, \phi}$ or six distinct symbols if I have to express any differential coefficient of E, and if I have to express all the differential coefficients of v I must use other six symbols; altogether I must use thirty of these curious symbols instead of five common letters, and, furthermore, I must keep them all in my head. JOHN PERRY.

The First Magnetician.

WHILE thanking you and "R. T. G." for the exceedingly kind appreciation of the Gilbert Club's English translation of "De Magnete" (p. 249), I write to express the wish that the notice had mentioned the names of those who have collaborated in the production of this version. They are the late Mr. Latimer Clark, the late Sir B. W. Richardson, Rev. A. W. Howard, Prof. R. A. Sampson, Dr. Joseph Larmor, Sec. R.S., Prof. Meldola, F.R.S., Mr. Edward Little, Mr. G. T. Dickin and Rev. W. C. Howell. To the last-named a special recognition is due for indefatigable and critical care during the long final revision and press correction.

July 14. SILVANUS P. THOMPSON.

"Fox-shark" or "Thrasher" (Alopecias vulpes) in the English Channel.

ON July 2 a fine specimen of this shark was captured several miles south of the Eddystone Lighthouse by fishermen in search of mackerel. The fish was taken at a depth of about 40 fathoms, and did a large amount of damage to the mackerel nets before it could be hauled on board and killed. The shark was brought to the Plymouth Museum and purchased for the collection.

It may be worth while to state that the spiracles, which Couch says he was unable to detect, are distinctly visible in this specimen. It is scarcely surprising that they should be sometimes overlooked, for though our fish is 13 ft. (thirteen feet) 7 in. (seven inches) long (of which the tail occupies seven feet), the spiracles are only 1/12th (one-twelfth) of an inch long by 1/16th (one-sixteenth) of an inch wide. Each is situated exactly $2\frac{1}{2}$ (two and a half) inches behind the eye, and a line from the spiracle to the tip of the snout passes just above the centre of the pupil. E. ERNEST LOWE.

Plymouth Museum, Plymouth.

THE TRAMWAYS EXHIBITION AT THE AGRICULTURAL HALL.

THE International Tramways and Light Railways Exhibition which came to an end on Saturday last must be regarded as having been very successful from all points of view. The opening ceremony was performed by Mr. Gerald Balfour on July 1, and was accompanied by the usual luncheon and speeches. Mr. Gerald Balfour alluded, as might have been expected, to the recent deputation to his Department on the subject of electrical legislation, but he did not evince any sign of having become convinced of the necessity for speedy reform. In other respects the speeches were not of much interest; the same may be said to be true to a certain extent of the proceedings of the International Tramways and Light Railways Congress, which held its meetings on July 1 and 2. The Congress, which was the twelfth held by the Union internationale permanente de Tramways, was the first to be held in London; the papers read and discussed dealt with the management and technical details of tramway schemes, and were most of them contributed by the engineers or managers of continental tramways. Many of them were very valuable, especially as they were based on the results of wide practical experience, but we doubt if they would prove of great interest to the readers of NATURE.

The exhibition itself contained a number of very attractive exhibits. Although primarily a general exhibition of all things pertaining to tramways, there was much on view which was of the greatest interest to those having nothing to do with traction. It was also very noticeable that the exhibition resolved itself practically into one of electric tramways. Of course, there was much that was not electrical—such, for example, as rails, points, &c.—but these are all part of the equipment of an electrical system. And perhaps the general impression with which one left the hall, that a "tramway" was necessarily the same thing as an "electric tramway," was of more interest, as a sign of the times, than were any of the individual exhibits.

Several different types of car were on view; the one which, not unnaturally, attracted the most attention was that constructed by Messrs. Dick, Kerr and Co. for the London County Council. This is the first of one hundred cars being built for the Council's South London Tramways. The car is double-decked, and has a total seating capacity of sixty-six (twenty-eight inside and thirty-eight outside), and is equipped for the conduit system to be used on the South London lines. The Westinghouse Company exhibited a car which ran over a fully equipped trolley line laid along the total length of the hall, a distance of more than 300 feet. Power was obtained for running this from a 75 kw. direct-current generator (500 volts), driven by a Westinghouse three-cylinder gas engine. The car was fitted with the Westinghouse magnetic brake. This brake has a triple action, acting as a wheel-brake, a track-brake and an axle-brake; it is energised by current derived from the car motors, which work as generators whilst the car slows down, the necessary energy being derived from the momentum of the car. The action of the brake is therefore independent of the main current supply.

A notable feature of the exhibition was the Bremer arc lamp, exhibited by the Westinghouse Company. This lamp was used for part of the lighting at the Natural History Museum on the occasion of the Institution of Electrical Engineers' conversazione. Unfortunately, it did not create a very favourable impression there, as the lamps kept flickering; those at the Agricultural Hall seemed to be burning much better. The carbons used in the Bremer lamp are saturated with certain minerals which volatilise and become incandescent in the arc; they are, moreover, arranged nearly parallel to one another instead of vertically one above the other; the ends project a little below a protecting hood, meeting at an angle of about 20°, and the arc is kept at the tips by means of a magnetic deflecting device. The position of the arc, the materials used in the composition of the carbons, and the reflecting power of the conical hood, combine to produce a highly efficient light. It is said that the lamp is three times as efficient as an ordinary arc. The colour of the light is also much pleasanter and warmer than that of the ordinary arc, and the light appears to fill the globe much better, with the result that it produces somewhat the effect of a golden ball of light.

Another similar arc lamp exhibited was that of the Union Electric Company. This, which is called the "Flame" arc lamp, has vertical carbons like an ordinary lamp; the carbons are, however, cored with a mixture of certain fluorides, and the upper one passes through a

dome-shaped hood, which is fixed a little above the arc itself. A rather long arc is burnt, and the effect is very similar to that produced by the Bremer lamp, only the light is of a slightly different colour. This lamp is also said to be three times as efficient as an ordinary arc.

We have not space at our disposal to describe the exhibits fully. There is one other, however, which deserves special comment on account of its ingeniousness and possibly great importance. This is the Partridge "Sparklet" fuse, exhibited by Messrs. Elliott Brothers. This fuse is designed more especially for high-tension circuits carrying heavy currents. When the fuse in such a circuit goes an arc forms, and in order to prevent this burning, either a very long fuse or some form of oil fuse is used. In Mr. Partridge's "Sparklet" fuse a short length only is used, and the terminals of the fuse wire are connected to an ordinary sparklet such as is now a familiar article for making soda-water. The arc when it forms burns between the two sparklets, and in a very few seconds one or other of these is burnt through; the carbon dioxide immediately rushes out through the hole and blows out the arc. It will readily be understood that the more current the circuit is carrying, and the more power there is in the arc, the sooner will the sparklet burn through, and also the hole being larger the more certain it will be in its action. At the Agricultural Hall a model fuse was shown working a circuit of 2500 volts. The current was small, only about 6 amperes, the power being therefore about 15 kilowatts; yet the arc was blown out in less than three seconds. Two sparklets are used, one at each end of the fuse, in case one should be defective; but this precaution has never been found necessary during all the experiments and trials that have been carried out. For the past eighteen months the apparatus has been in practical use, and has proved, it is said, thoroughly satisfactory. Mr. Partridge is certainly to be congratulated on a very ingenious idea; it remains to be seen whether it will prove a sufficient cure for all the troubles that are likely to be met with now that large-power high-tension circuits are becoming common. M. S.

THE ASTROGRAPHIC CHART.

IT is probably well known, even to those who are not astronomers, that an astronomical enterprise of considerable magnitude was initiated fifteen years ago, and is steadily, although somewhat slowly, progressing towards completion. In the year 1887 a conference of astronomers met at Paris to consider the best means of cooperating to make a complete map of the heavens on a large scale, and with all possible attention to accuracy, by photography. As the outcome of this conference, eighteen observatories of various nationalities undertook the work, the whole sky being divided up into eighteen zones; a zone assigned to each observatory with due regard to its geographical position. A standard pattern of photographic telescope was chosen, and all the eighteen observatories obtained instruments of the required type and set to work. The enterprise being in several respects entirely new, it has been necessary to guide the procedure in the light of experience acquired; and conferences assembled at Paris in the years 1889, 1891, 1896 and 1900 to report progress and compare notes. At the last of these conferences a second enterprise was undertaken. The small planet Eros, discovered in 1898, was to make a particularly close approach to the earth in the winter of 1900–1, thus affording an opportunity, the like of which would not recur for thirty years, of determining the solar parallax; it was felt that, although the main object of the association of observatories (viz. the formation of the Astrographic Chart) was not yet attained, still the advantages to astronomy which would result from utilising this exceptional opportunity were too great to be neglected, and it was resolved that the cooperating observatories should add to their programme the photographic observation of the little planet during the months October 1900 to February or March 1901. In connection with this second enterprise it has been found necessary to circulate a large amount of statistical material, such as approximate positions of the planet on different dates and of all the well-known stars lying near his path in the heavens, lists of the observations made at the different observatories, so that one might know how to match plates with another, and so on. The energy of the director of the Paris Observatory (who has from the first acted as director of the whole work) in printing and circulating this material has been most noteworthy. We have recently received the *ninth* circular relating to Eros, which is itself a pamphlet of 200 pages quarto, and represents a vast amount of work. In the first place, M. Lœwy discusses, in two long memoirs (supplementing a former one already published), what accuracy is obtainable from measures of photographic plates and what precautions are necessary to obtain that accuracy. The discussion is concerned with a number of minute details, and involves the adjustment of conflicting advantages, so that there is room for difference of opinion in the conclusions; but there can be but one opinion of the value of the material patiently collected and tabulated by M. Lœwy, which can be examined in the light of any hypothesis preferred. The second part of the ninth circular gives, among other useful information, ephemerides of the planet Eros and of the sun, calculated to eight significant figures for every six hours—almost a new departure in such work, the only precedent being afforded by the investigations of Sir David Gill on the planets Victoria, Iris and Sappho, whereby he clearly showed that eight figures were necessary to represent the accuracy of heliometer measures. To advance one decimal place is of course a step of the gravest importance, and to Mr. Hinks, of the Cambridge Observatory, belongs the credit of being the first to show that an accuracy can be obtained from photographic measures of the Eros plates of the same order as that which led Sir David Gill to ask for an eight-figure ephemeris.

The appearance of so much important literature in connection with this second enterprise, the photographic observation of the planet Eros, naturally suggests a glance at the state of affairs with regard to the main work, the Astrographic Chart itself. It is, as remarked in the first sentence of this article, some fifteen years since the work was initiated, and it should by this time be possible to form an estimate of the probable outcome and the approximate date of completion. It must be confessed that the original estimate of the time required has already been seriously exceeded. In the letter which summoned the conference of 1887 it is stated that:—

"Ce grand travail . . . pourrait être facilement exécuté en quelques années si dix ou douze observatoires bien répartis sur le globe pouvaient se partager convenablement la tâche."

The phrase "quelques années" is somewhat indefinite, but it may be assumed that those who assembled in 1887 would have been shocked to learn that after a lapse of a dozen years scarcely one-fifth of the work projected had been accomplished. Indeed, many who are tolerably familiar with the general course of events may be startled to hear this statement made; and yet a glance at the last comprehensive report available (see R.A.S. *Monthly Notices*, vol. lxi. p. 280) shows it to be only too true. It was decided to work on such a scale that 11,000 plates would be required to cover the sky, and this number was to be repeated four times, twice with short exposures (of 6 minutes, 3 minutes and 20 seconds), and twice with long exposures (40 minutes). The plates of the first series (catalogue plates) were to be measured, and the measures printed and published; those of the second series

(chart plates proper) to be reproduced in facsimile. In June, 1900, the state of affairs was as follows:—15,000 of the 22,000 catalogue plates had been *taken*, but only 4000 had been measured; and the measurement is of course by far the most serious part of the work. Of the 22,000 chart plates required, less than 4000 had been taken, and only a small portion of these had been reproduced and published. So that the fraction of the whole programme accomplished in a dozen years can certainly not be put higher than one-fifth.

Does this mean, then, that it will take sixty years to finish the whole? It is earnestly to be hoped that this would not be a legitimate inference, and fortunately there are good sound reasons why it should not be. The years immediately succeeding 1887 were naturally devoted to experimental work, of which a large amount has been necessary. This was foreseen at the outset; witness, for instance, the words of the veteran Otto Struve in his opening address:—

"En effet, l'Astronomie pratique possède aujourd'hui, dans la Photographie, un instrument de la plus haute valeur et qui, probablement avec le temps, facilitera énormément nos études épineuses. Mais restons sobres dans nos prévisions. Pour le moment, nous ne devons regarder la Photographie que comme un instrument très précieux, *mais dont l'étude reste encore à compléter*."

But it will probably be agreed that the amount of work necessary to "complete the study" has exceeded expectation.

Beyond the preliminary experiments which might have been foreseen by an individual worker, much time has been spent in a well-meant endeavour to secure uniformity in the work, which has, after all, not been very successful. Thus a large part of one year was lost in attempts to devise an obscuring screen which should diminish the light received from the stars in a known ratio, and ultimately secure uniformity in the limiting brightness (or rather faintness) of the stars charted; but this attempt was at last abandoned in favour of the simpler method of fixing a definite time of exposure, which might have been adopted from the first. Or going further back in the history, it must be remembered that although a standard pattern of telescope was adopted in 1887, it took a considerable time, not only to make the eighteen instruments required, but for the makers to find out how to make them. Thus it would be fair to estimate that in 1900 the work had been in actual progress, not for a dozen years, but for less than half that period; so we need not fear that the completion of the work is still half a century off. Nevertheless, he would be sanguine who should reduce this prospective limit below twenty years, unless some very drastic measure is adopted in the near future. Some of the cooperating observatories are well advanced with their work, but others are far behind. In 1900 there were actually three which had not started at all, and these have been struck off the list and replaced by three new ones. We have good reason for anticipating energetic action from these new comers, but it must be remembered that they start a dozen years at least behind their colleagues.

This great delay in the execution of the work has been prominently mentioned because it demands most serious attention if the original scheme is to be carried out in any real manner. Even without the addition of the Eros work there was sufficient cause for anxiety; with that important and unforeseen addition there is reason for alarm. It is to be hoped that the dangers may be realised and obviated within the next few years.

But when we turn to the contemplation of what has been accomplished, there is good reason for satisfaction. To take first the series of catalogue plates, with short exposures of a few minutes only. Each observatory has to take about 1200 of these, and the area of the sky covered by each is a square of two degrees in the side, so that sixteen full moons arranged in solid square formation would just about cover this area. On each plate there are some 300 or 400 star-images on the average; but this is an average from which the deviations are large. A plate exposed near the Milky Way, even for a few minutes only, shows thousands of stars, whereas if the telescope be pointed to a region distant from the Milky Way, the number may fall below 100. Taking the average as 350, there are on the 1200 plates which form the share of one observatory some 400,000 star-images; and it is the business of that observatory, after taking the plates, to measure carefully the relative positions of all these images and publish the results. Moreover, it has been found advisable to make these measures at least twice over, so that we may put the total number at something like a million. It will readily be conceded that this is a gigantic piece of work for a single observatory to carry out, and it is a great thing to be able to say that some of the observatories are already in sight of its accomplishment. Others, as has been admitted, have not yet commenced the work, but they will enter upon it with all the advantages of following an example already set, and we may consider that the greatest difficulties have been overcome.

This portion of the work affords another reason for satisfaction. Mention has been made of some preliminary experimental work which produced no positive result, but other such investigations have had more fortunate issues, especially the research on the best method of measuring the plates. In 1887 there were at least three different methods which might be adopted, and corresponding to each of these there was a choice of patterns for the instrument to carry it out. The proper method for measuring stellar photographs has now been practically settled, and though there is diversity of opinion as to the best actual instrument, the relative advantages of the different forms are becoming tolerably well known. It will be realised how definite an advance has here been made when it is remembered that an eminent astronomer, in reviewing the possibilities in 1887, dismissed the method which has since been universally adopted as obviously inferior to the others and not worthy of consideration. The test of experience had, in fact, not been applied, and the result of its application may be regarded as a valuable scientific asset.

Let us turn now to the other set of plates, the chart plates as they are called, similar in every way to the catalogue plates, except that they are exposed to the sky for a much longer time (forty minutes at least, instead of three or six), and hence contain thousands of stars instead of hundreds. It is proposed that these plates shall be reproduced on paper by some process which depends on the automatic action of light only, and is thus free from the imperfections incidental to human agency. The exact process has not been formally specified, and it is open to any observatory to circulate ordinary contact prints, for instance, if such can be made without losing too many of the fainter star-images. Up to the present time, however, the only reproductions of chart plates which have been published are in heliogravure. The French observatories (Paris, Algiers, Toulouse, Bordeaux) and the Observatory of San Fernando, in Spain, have produced and circulated most beautiful enlargements (twice the linear dimensions) of some of their chart plates made by heliogravure, and there are many reasons why we may hope that their example will be universally followed. To begin with, the charts are really beautiful to look at—as might be expected from the French, they have produced something æsthetically satisfactory. Secondly—a matter of infinitely more importance astronomically—the charts

are wonderfully accurate. It has been shown that the places of stars can be measured from them with an accuracy almost equal to that obtainable from the original glass negatives. Finally, they are presumably permanent—far more so than the glass negatives, unless the toning process recently suggested by Sir William Crookes is adopted and found as successful as is expected. Against these manifest advantages is, unfortunately, to be set the costliness of the process. It is estimated that to reproduce its 1200 plates in this way each observatory must have a sum of about 10,000*l.* at command, independently of the actual time spent in the work. This sum is large, but not prohibitive. Five observatories are apparently already provided with it; in the interests of uniformity in a magnificent piece of work, may it be hoped that in some way or other the remaining shares will be taken up? If the paper reproductions were (as it was at one time supposed they would be) mere playthings of no scientific value, such expenditure might have been deprecated. But it has been demonstrated that they are accurate beyond expectation, that, in fact, an observatory provided with copies of this kind for the whole sky could in a few minutes obtain the place of any star down to the 14th magnitude with an accuracy equal to that with which the best meridian observations can be made. It seems probable that the outlay is as good a one as can be made with our present imperfect knowledge of the requirements of the future.

The consideration of what this means in actual weight of paper brings home to us in a striking manner the magnitude of the whole enterprise. If the 22,000 maps are completed in the style adopted by the French, the sheets when piled one on the other would form a column thirty feet high and weighing nearly two tons! The most elaborate star atlas which has been produced up to the present time can be bound as a single, though rather large, volume, which could be added to any library without sensible disturbance. But not so with a copy of the Astrographic Chart; it is a matter for the serious consideration of each fortunate possessor where and how he shall store the sheets and ensure their preservation. There is not likely, of course, to be any real difficulty in doing this, the point is only mentioned here to illustrate the novelty of the departure rendered possible by photography.

As there is an obvious danger of not being able to carry out this vast programme (for which, it will be remarked, not only scientific labour, but much hard cash is required, and the latter may not be easy to extract from reluctant Governments), it is reassuring to know that there is at least one good alternative. We might carry out the work much more economically with a different type of instrument, though at the cost of some obvious advantages. The type selected in 1887, a refracting telescope of 11½ feet focal length, allows us to photograph an area of the sky at one exposure limited to two degrees square, and 11,000 plates are required to cover the whole sky. Two other types were considered and rejected. The first was the reflecting telescope, with a concave mirror in place of a lens. The area satisfactorily photographed at one exposure with a reflector is even smaller, and the number of plates required for the whole sky consequently greater. Though the reflector has distinct advantages in cheapness and in light-grasping power which have recommended it for other classes of work, there is no doubt that it was rightly rejected for the Astrographic Chart; all our experience subsequent to 1887 has tended to confirm this view. The third possibility open to the conference of 1887 was the use of a doublet lens, such as is familiar in an ordinary camera. The lens of a camera is made up of two lenses (each of which is itself double) separated by a definite interval, where a "stop" may be inserted. A photograph could be taken with one of these lenses alone, but only a comparatively small portion of the picture near the centre would be in good focus; the combination is made to give a larger "field." If such a doublet lens is used to photograph the sky, we get a much larger field at one exposure, and can cover the sky with fewer plates. The claim has recently been made that twenty or thirty plates would suffice to cover the sky instead of 11,000! Of course the results would be on a correspondingly smaller scale, and this extreme procedure is not to be contemplated as an alternative to the large and accurate charts with which a start has already been made. But if we could reduce the 10,000*l.* required to (say) 1000*l.*, we are in the region of the possible or even the probable, and this only means reducing the number of plates required in the ratio of one to ten, or increasing the area covered by each in the same ratio. We may take it as fairly well established that a doublet will satisfactorily cover a field at least ten times as large, in area of the sky, as the single lenses at present in use for the work of the chart.

The question naturally arises whether these facts were realised in 1887, and if so, how the single lens came to be preferred to the doublet. The discussion on the type of instrument to select took place on April 18, 1887, and the *procès-verbaux* are given on pp. 36–43 of the official account of the conference. Twenty-six distinguished astronomers were present, and eighteen of them took part in the debate. *The photographic doublet was not even mentioned.* At the present time this circumstance is almost bewildering. At the end of the volume a letter is printed from Prof. E. C. Pickering (who most unfortunately was not able to attend the conference) advocating the use of the doublet, and giving detailed suggestions for the whole work which commend themselves, in the light of subsequent experience, as admirable. But his views received no attention; the debate was confined almost entirely to the relative advantages of reflectors and refractors, and the proper size to be adopted for the latter, and it must be confessed that an opportunity was lost. Since that time Prof. Pickering, using doublets, has charted the whole sky himself many times over, while the associated observatories have not yet accomplished a third of their programme. It must not be forgotten that their programme includes much more than the mere charting of the sky, viz. the measurement of some plates and the reproduction of others; but even making this allowance, the discrepancy between what he has done single-handed and what has been done on the plan preferred at Paris in 1887 is sufficiently serious.

The fact is that astronomers generally were afraid of the doublet in 1887, and some of them have not yet lost their mistrust. They were afraid that so fair a promise was too specious; that, in fact, the gain in extent of field over the refractor must be accompanied by a corresponding loss in accuracy. At the time no definite information was forthcoming on this point, and it must be admitted that even now our knowledge is far from complete. It is not so easy as it might seem to test pictures of the stars for the minute accuracy necessary to an astronomer, and it may still be proved that the choice of the refractor in 1887 was, from the point of view of getting the greatest attainable accuracy, a wise one. But, on the other hand, it has been shown that the mistrust of the doublet was largely unjustifiable; its accuracy is of a high, if not of the very highest, order. It is not even now too late to follow the excellent advice which was offered in 1887 only to be ignored. By adopting the doublet the chart plates might be completed in a reasonable time and at a reasonable cost, though on a smaller scale.

H. H. TURNER.

SOME NEW FORMS OF GEODETICAL INSTRUMENTS.

THE optical principles involved in gun-sighting apparatus, described in the issue of NATURE for January 9, 1902 (p. 226, vol. lxv.), have been further developed by Sir Howard Grubb, F.R.S., and applied to some new forms of geodetical instruments. In the gun-sighting apparatus alluded to, a virtual image of an illuminated cross is optically projected on to the object aimed at, and both the cross and the object are easily seen without any refocussing or straining of the eyes. In the case of the gun sights and also the present instruments, light traverses a plate of glass coated with a very thin film of galena; by this means reflection of light from the surface of the glass is greatly increased, while but little transmitted light is shut off. The process of depositing galena is due in the first instance to Prof. J. Emerson Reynolds, F.R.S.; it is described in the *Proc. Chem. Soc.* for 1884, under the heading "The Synthesis of Galena by means of Thiocarbamide."

The process has been modified by Mr. G. Rudolf Grubb and applied with great success to some new forms of surveying instruments. These instruments have not

FIG. 1.

been designed to take the place of the standard instruments of the engineer, namely the level and the theodolite, but to place in the hands of comparatively inexperienced observers, a ready means of making a rapid survey with an accuracy as great as can be attained in plotting a survey on paper. In the case of ordinary surveying, for example, in road making and in the conveyancing of property, the accuracy of the survey is limited by the degree of precision with which it can be actually plotted on paper with a pencil giving fine lines. When the theodolite is used, the readings are first entered in the field book and then afterwards plotted on paper, the angles being set off with a protractor. By means of the new instrument, the survey is continuously plotted as the instrument is being used. In Fig. 1 the new form of plane table is shown. The central pillar, through which the successive bearings are taken, is shown in section in Fig. 2; it is mounted on a triangular base, or set square, which can be rotated about a point situated in the centre of the paper on the plane table. The instrument is used thus. The sight tube is rotated until its fixed line coincides with a given object, a line is then ruled, it is again moved through some angle till the line coincides with a second fixed object, and another line is ruled along the edge of the set square, the process being repeated until the position of the last fixed object is recorded. Then the whole plane table is moved to a fresh station at a measured distance from the first station, and similar observations are made on the same fixed objects; the intersections of the two sets of bearings give the points

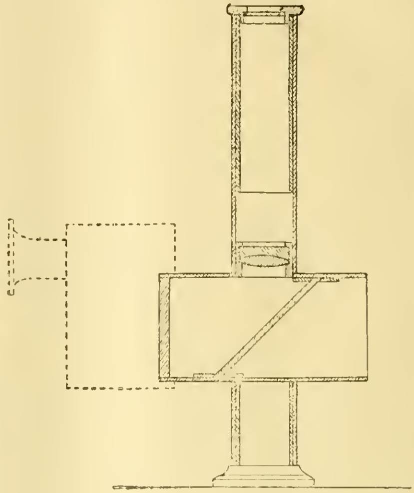

FIG. 2.

required for the survey. In the case of the survey of a small area, the instrument is not shifted to a new station, but the distances corresponding to the ruled lines are determined by reading the number of divisions which appear in the field of the instrument between two marks

FIG. 3.

of known distance apart on a staff held at a fixed point. The instrument thus becomes a telemeter, and by means of a suitable scale the distance along any given direction is found and marked on the paper. The actual method of using the instrument is as follows:—The staff man

walks round a field and successively plants his staff upright where a change in the directions of the boundary occurs; at each point the observer at the plane table rules the direction line and marks the distance, repeating the operation for each successive point, so that the survey of the field is made during the time taken by the staff man in walking round the field and making the necessary halts at each point for the observation to be recorded. The scale and view photographed through the plane table instrument is shown in Fig. 3.

The same optical principle has also been employed by Sir Howard Grubb in the construction of a level to be used in making rapid estimates of gradients in road making and laying out property.

The observer sees at the same instant a fiducial mark, the bubble of the level, and an arc marked with degrees projected on to the field of view.

The excellent optical device has also been utilised in the construction of a prismatic compass and a clinometer.

M. HERVÉ FAYE.

ALL who have taken any interest in the advance of science, more particularly in the direction of astronomy and meteorology, will hear with regret of the death of M. Hervé Faye, which sad event was announced last week. A long course of scientific industry has marked his career, and a great distance seems to separate the workers of to-day from the epoch when Faye and many others, whose names are now but a matter of history, laboured strenuously and successfully to make the paths for their successors more easy and of more rapid attainment. Nearly sixty years have passed since M. Faye first came prominently before the world as the discoverer of a comet, to which his name has always been attached, and it will serve to make us appreciate the advance accomplished in one lifetime if we recall the fact that this was the first elliptic comet the period of which was determined by calculation alone, without any assistance drawn from observations made at previous returns. Faye, at that time an assistant in the Paris Observatory, recognised the necessity of computing an elliptic orbit, but the credit of determining the first orbit of considerable eccentricity from a few days' observations belongs to Goldschmidt, who was stimulated to the task by Gauss. Then the information and the methods of the *Theoria Motus* had not filtered through a score of text-books and come into the hands of numberless computers, whose deftness of calculation had been whetted by the discovery of hundreds of asteroids, the orbits of which stood in need of determination.

But it will be rather on his philosophical writings than his scientific observations that the reputation of Faye will rest and be honoured by his countrymen. It may be that to some of his theories a general assent has not been given, and that in some cases later discoveries have modified the views the distinguished physicist expressed, but no doubt will be entertained concerning the clearness and ability with which those views have been uttered, or of the influence they have had on French thought. Ever since the time that Laplace in a few pregnant sentences sketched the plan on which the solar system might have been constructed, the subject has been a favourite speculation among French physicists. M. Faye has not been able to resist the temptation to attack this subject, and though, like all attempts at universe construction, the scheme of M. Faye fails to meet all the difficulties which beset the problem, yet it is a most suggestive contribution to the subject, and should prove an incentive to further inquiry. In some respects this cosmogonic theory contrasts very favourably with that of Laplace, and in others, as was natural, it falls behind that of his great predecessor; but this is not the place to enter into any details or criticisms of the argument developed. In recalling, however, the services which M. Faye rendered, one would not willingly forget this finished essay ("Sur l'Origine du Monde"), in which is given, with much that is suggestive, a lucid explanation of the state of our knowledge of the solar and stellar systems.

Similarly, it would be out of place to discuss here the views he expressed on the constitution of the sun, the causes of sun-spots, the behaviour of solar prominences or the chemistry of the sun generally. All these are subjects that fell under Faye's notice and which he treated broadly and philosophically, but necessarily without the facts and knowledge that later observations have brought to light. In cosmical physics and chemistry he was to a great extent a pioneer, and if his theories are in some cases for this reason insufficiently supported by exact observation, they are generally characterised by a breadth of view and thoroughness of conception that contrasts favourably with contemporary opinion. In the discussion of problems connected with cosmical meteorology, or with the motions of our own atmosphere, he was, perhaps not so happy, and his writings on cyclonic motions, the laws of storms, the behaviour of tornadoes, and the exceptional phenomena which we occasionally experience will probably be soon forgotten. Not so, however, with such works as the "Cours d'Astronomie nautique" and other mathematical books with which he has enriched French literature, and which are models of arrangement and of clearness of expression.

One could with difficulty recall the numerous services which M. Faye rendered to his Government or the acknowledgments that he received from foreign scientific bodies. He was, of course, Membre de l'Institut and besides a seat at the Bureau des Longitudes which he had occupied since 1862, in succession to Biot, he was called by Marshal MacMahon to fill in his Cabinet the office of Minister of Instruction, at a time when it was thought not impossible that M. Faye might have become Director of the Paris Observatory in succession to Le Verrier. He was elected a Foreign Associate of the Royal Astronomical Society so long ago as 1848, while Belgium, Venice, the United States of America enrolled him among the members of their scientific societies. Full of years and distinction he is removed from us, and with him another link that connects the science of to-day with the science of the past.

W. E. P.

NOTES.

THE new botanical laboratories of the Chelsea Physic Garden are to be opened by Earl Cadogan at a garden party there on Friday, July 25.

A REUTER telegram from Kronstadt in yesterday's *Times* reports that on July 14 the Italian cruiser *Carlo Alberto* received, for the first time, messages by wireless telegraphy from the Poldhu station in Cornwall. These are the first experiments in wireless telegraphy over a distance of 1600 English miles in a straight line by land, and the results are said to have been most successful, the messages received having been very distinct.

AMONG the Civil List Pensions announced in a Parliamentary Paper just issued are the following:—Mr. W. H. Hudson, in recognition of the originality of his writings on natural history, 150*l.*; the Rev. Dr. John Kerr, F.R.S., in recognition of his valuable discoveries in physical science, 100*l.*; Mrs. S. C. Jones, in recognition of the services rendered by her late husband, Principal John Viriamu Jones, to the cause of higher education in Wales, 75*l.*; and Mr. H. Ling Roth in consideration of his services to anthropology, 70*l.*

THOUGH the damage done in Salonica by the earthquake which occurred there on the afternoon of July 5 (see p. 254) was not great, some of the surrounding villages suffered considerably. At Guvezno 150 houses were wrecked and at Karajere fifty houses were destroyed. A new spring burst out at the mineral baths of Langaza. The shock was recorded at the observatory of Laibach, which is about 560 miles north-west of Salonica, and also in Birmingham, about 1440 miles in the same direction.

THE current number of the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale* contains the programme of prizes proposed by the Society for the present year. Among these may be noticed a prize of 2000 francs for the invention of a cement capable of agglomerating diamond dust for mechanical purposes, another of 3000 francs for a steam superheater fulfilling certain conditions, and one of 2000 francs for any important progress in the mechanical transmission of work. In chemistry a prize of 1000 francs is offered for the utilisation of a bye-product, and medals for publications useful to chemical industry or metallurgy. A prize of 2000 francs is offered for an apparatus suitable for domestic use capable of sterilising drinking water by boiling, one of 2000 francs for a study of the alcoholic ferments and diastases, and one of 1000 francs for freeing the vine from an insect parasite. In political economy, a prize of 3000 francs is offered for a study of the effects of trusts and industrial syndicates generally upon production and sale.

SEVERAL eruptions of Mont Pelée occurred last week. On July 9 a disturbance began at 7.30 p.m. and continued until midnight. From the *Times* we learn that a column of black smoke streaked with lightning was first observed, and that this was apparently followed by flame, which set fire to the ruins of St. Pierre. Stones and ashes fell for 25 minutes on Morne Rouge and Fonds St. Denis. Drs. Anderson and Fledd were thought to have been overwhelmed by the ejected matter, but they arrived safely at Fort de France on July 11. They were on board a sloop which was lying off St. Pierre when the eruption occurred. A message from St. Thomas states that three loud detonations were heard from the Soufrière, St. Vincent, between 8 p.m. and 9 p.m. on July 9. Advices from Barbados state that loud detonations were also heard there on the night of July 9, in a westerly direction. A telegram from Fort de France states that about midnight on July 12 there was a third violent eruption of Mont Pelée. Large quantities of stones and ash fell on Morne Rouge, Macouba and Ajouba Bouillon. The French scientific mission, which arrived the day before from Guadeloupe, whence it had been recalled by the Governor, left on July 13 for St. Pierre.

M. F. A. FOREL describes, in the *Journal Suisse* of July 10, some brilliant sky effects observed by him at Morges on July 5 directly after sunset. A brilliant disc of light of a whitish-yellow colour appeared thirty degrees above the sunset point a quarter of an hour after the sun had set, and lasted for a quarter of an hour. Ten minutes later a purple circle sixty degrees in diameter appeared, and sunk lower and lower as the sun increased its distance below the horizon. While this circle was visible the sky was brightened by an after-glow. The red sunset effects observed at Jamaica on May 25, Madeira on June 10, and Bombay about June 25 had not been seen at Morges on July 8.

IN the July number of the *Bulletin de la Société Astronomique de France*, M. Flammarion gives the first instalment of a history of the West Indian volcanoes, with special reference to Mont Pelée and the recent eruptions. The article is illustrated by photographs and charts, and contains letters of pathetic interest written a day or two before the great eruption, which show that at least some of the inhabitants of St. Pierre, including several members of the Société Astronomique, feared the possibility of a disaster several days before the final catastrophe occurred.

MR. PIERPONT MORGAN has bought and presented to the Paris Museum of Natural History the collection of precious stones formed by Mr. Kunz, of New York, for the Buffalo Exhibition of last year. He has also sent to the American Museum of Natural History in New York a large star sapphire and a beautiful yellow sapphire. These gems will be added to the collection of precious stones previously presented by Mr. Pierpont Morgan to the Museum.

THE expedition to the Malay Peninsula undertaken by Mr. N. Annandale and Mr. H. C. Robinson with the aid of grants from the Government Grant Fund and Edinburgh University, has now concluded its field work, and it is hoped that a preliminary notice of its more important results may be presented to the British Association at Belfast. A complete series of anthropometrical measurements, representing more than 300 individuals of the various races "wild" and "civilised" inhabiting the Siamese Malay States and Perak, has been obtained, with numerous photographs and about thirty authenticated skeletons and skulls, nearly two-thirds of which belong to the primitive peoples known as "Sakais," "Semangs," and "Orang Laut" respectively. Studies have been made of the religions, burial customs, and sociology of these races, and collections of their clothing, weapons, utensils, and magical and musical implements made. The zoological results comprise extensive notes on mimicry and kindred phenomena and a series of photographs of insects and other animals in their natural surroundings as well as general collections from both high and low levels.

IT was recently reported that Dr. Doberck was retiring from the directorship of the Hong Kong Observatory; but we understand this is not the case and that he is merely home on sick leave.

A TELEGRAM from the Viceroy of India, dated July 12, reports:—"Good rain has fallen over the greater part of India, but fall light in Burma, in Southern India, Southern Punjab, in parts of Rajputana and Sind."

A BRITISH and Colonial Industrial Exhibition will be held at Cape Town for a period of four months from November 1903. All the necessary funds have been guaranteed, and a site adjoining the Botanic Gardens has been chosen. It is important that British manufacturers should participate in a scheme which offers a good opportunity of bringing their products and wares before the South African public, especially in view of the inroads made by foreign competitors in the South African market. When the exhibition is open the industries of farming, dairying, and wine growing will be busy in schemes for a fresh start. The exhibition of the latest and most up-to-date appliances, tools, mechanism and machinery should, therefore, lead to very extensive business, and the opening of new and permanent trade outlets for Imperial manufactures.

THE preliminary programme of the nineteenth congress of the Sanitary Institute, to be held in Manchester on September 9-13, has now been issued. The president of the congress is Earl Egerton of Tatton. Dr. W. N. Shaw, F.R.S., will deliver the lecture to the congress and Sir W. J. Collins will deliver the popular address. The three sections and their presidents will be:—(1) Sanitary science and preventive medicine, Sir James Crichton-Browne, F.R.S.; (2) engineering and architecture, Sir Alexander Binnie; (3) physics, chemistry and biology, Prof. A. Sheridan Delépine. There will be eight special conferences of municipal representatives,

port sanitary authorities, medical officers of health, engineers and surveyors to county and other sanitary authorities, veterinary inspectors, sanitary inspectors, domestic hygiene, and hygiene of school life. In connection with the congress, a health exhibition of apparatus and appliances relating to health and domestic use will be held, as a practical illustration of the application and carrying out of the principles and methods discussed at the meetings.

THE announcement that the meteorological observatories on Ben Nevis and in Fort-William will have to be closed at the beginning of October next, in consequence of the want of funds to keep them in operation, will be received with regret by many meteorologists and other men of science. During the last four years the liberality of Mr. Mackay Bernard, of Dunsinnan, made the continuation of the work at the observatories possible, but there is no hope, in the opinion of the directors, that the observatories can be continued as permanent institutions except by assistance from the State. From the commencement of the work, in 1883, until now, the total cost has been fully 24,000*l.* Of this sum nearly 17,000*l.* has been received by the directors in the form of subscriptions. The balance of the expenditure has been met by a payment of 100*l.* a year, since 1883, from the Meteorological Council for the Ben Nevis Observatory, and of 250*l.* a year from the same body, since 1890, for the Fort-William Observatory. These two contributions constitute all that can be regarded as State aid. The directors have received definite intimation that, whether the observatories are continued or not, the latter sum —250*l.*—is to cease to be paid at the end of this year. In connection with this subject we notice that Sir John Stirling-Maxwell has notified the Lord Advocate that he will put a question this week in the House of Commons as to whether any application has been made through the Scottish Office for assistance for the observatory from the public purse, and whether, if such application has been refused, he will state the grounds of refusal.

AT the Aëronautical Congress held recently at Berlin it was concluded that no ascent should take place at a higher level than 7 or 8 kilometres without placing the observers within a closed car, "nacelle close," as was suggested, in 1871, by Mr. Louis Tridon. At that time a motion to this effect was rejected on account of the faith it places in the life-sustaining properties of pure oxygen. The scientific committee of the Aëro Club discussed this same subject on June 30 and came to the same conclusions. Dr. Henocque, professor of physiology at the Collège de France, said that the foregoing principles will be observed in the ascents now in preparation by the French Society of Physiology. He held that the atmosphere should be divided into three zones; that in the first, up to 4 or 5 kilometres above the sea-level, life was possible without the use of additional gas. For the third zone, at a level less than 10,000 metres, it would be necessary to resort to the closed car, or to an aërial diving suit. The ascents which Dr. Henocque arranged to take place on July 15, were to be executed entirely in the first zone. Investigation was to be made of the effects of the ascents within the limits of a depression consistent with life, or not ruinous to health, and in accordance with a series of observations made at the Eiffel Tower Dr. Henocque hopes to show that in this zone the ascents may be considered as beneficial to the general health, invigorating the lungs and likely to afford a remedy against some pulmonary affections. The conditions of life are not the same as when mountaineering, owing to the greater velocity due to the elevation and the absence of all muscular fatigue when the aërial traveller is comfortably seated in the car of a balloon.

ACCORDING to the *Times*, there is likelihood of large supplies of electrical and mining machinery being required shortly for Johannesburg, where an ex ensive electric tramway system is to be built. There is a desire to place orders as far as possible with British firms, but freights are very heavy, and British machinery requires therefore to be made lighter. Prompt delivery and lower prices are also needed to meet American and German competition; it is said that several orders have recently been secured by foreign firms at very low prices in order to secure a firm footing in the market.

A NEW oxygen-acetylene burner has been devised by M. Fouche (says the *Engineer*, July 11) which not only has a much higher temperature, but also the admixture of ether vapour is prevented. The ratio of the mixture is 1 volume of acetylene to 1·8 volumes of oxygen, and the flame, which is 6 mm. long, has a greenish dart in the centre with a point at a very high temperature. Iron and steel, it is claimed, can be easily welded without either oxidising or carburising the iron.

IN an Appendix iii. to the Weekly Weather Report for the year 1901, the Meteorological Council has recently issued a very useful set of tables showing for the stations which furnish returns for that Report and the monthly summaries, (1) the average maximum, minimum and mean temperatures for each month, and for the whole year for thirty years (1871–1900); (2) the average monthly rainfall and number of rain-days for thirty-five years (1866–1900); and (3) the average number of hours of bright sunshine and percentages of possible duration for twenty years (1881–1900). These tables are in continuation of those issued in the preface to the Weekly Weather Report for 1895, and furnish at a glance valuable information on the climatology of each of the districts into which the British Islands have been divided for the purpose of weather forecasts.

MR. W. E. COOKE'S report on meteorological observations made under his direction at the Perth Observatory and other places in Western Australia during the year 1900 contains an excellent collection of monthly and yearly climate and rain maps referring to the colony. One series of the maps shows for every month the mean pressures and temperatures and the mean maximum temperatures at day and minimum temperatures at night; also the annual means of the same records. In another series the amount of rainfall for every month of the year is shown graphically in each square degree of the colony, with the average rainfall for that district; and the distribution of the rainfall for the whole year is shown in the same way in a separate map. Mr. Cooke reports that the astronomical buildings of the Perth Observatory are now finished and the instruments in adjustment. The observatory is pledged to take a share in the preparation of the International Photographic Catalogue of Stars, but owing to want of assistants, it is difficult to obtain time for the work. The meteorological observations are, however, kept up at a fair number of stations, and the results for various localities throughout the State obtained since 1875 have been examined, tabulated and discussed, and will shortly be available in a volume entitled "The Climate of Western Australia."

MR. KUMAGUSU MINAKATA sends us from Japan two specimens, mounted as microscopic slides, of a fresh-water alga which he collected in a pond at Wakayama Shi, Japan. He desired to obtain an opinion as to the species, which he believed to be *Pithophora Oedogonia*, Wittrock, var. *vaucherioides*, Wolle, of which he possessed a quantity of specimens personally collected near Jacksonville, Florida, between 1891–92, well agreeing in detail with those submitted. He also remarked:— "Since the publication of Wittrock's elaborate monograph of the Pithophoraceæ, 1877, has any species, besides *P. Kewensis*, been ever reported from any other part of the Old World?" Prof. Howes, to whom we submitted the specimens, says in reply:—"I have no doubt that the Japanese identification is

correct. Mr. Rendle, with a former pupil of mine, Mr. W. West, jun., has described as new for Britain a variety of the genus from a canal in Manchester, where it was assuredly introduced (see *Journal of Botany*, vol. xxxvii., 1899, p. 289). I take his word as final. Mr. Minakata may be referred to the above-cited paper for the answer to his second question. *P. Kewensis* must have also been introduced, as it has never been found again."

PROF. T. LEVI CIVITA has contributed to the *Annales* of the Faculty of Sciences of Toulouse a paper having an important bearing on the recent discussions as to the production of a magnetic field by moving charges. In a previous paper on that subject, Prof. Righi had examined the possible sources of error in various experiments, from those of Rowland down to the recent observations of Cremieu and Adams, and had pointed out that some uncertainty was introduced by the presence of the conductor used to shield the magnetic needle from electrostatic action. This remark has led Prof. Levi Civita to undertake a mathematical investigation of the effect of an infinite plane-conducting screen on the magnetic field produced by an electrostatic charge moving uniformly parallel to the plane. The results which are embodied in the present paper show that if a is the ratio of the velocity of translation to that of light, then up to the order of a^2, the electric and magnetic forces on the side of the screen opposite to the moving charge are derivable from a potential. The electric force is negligible, while the magnetic force is reduced to a certain fraction, less than one-half, of what it would be at the same point if the conductor were removed. The magnetic force is not, however, entirely screened by the conductor except in the limiting case when the sheet has infinite conductivity.

THE unique construction of the "Cooke" photographic lenses, made by Messrs. Taylor, Taylor and Hobson of Leicester, has given rise to possibilities of variation of their focal lengths by the user, that are both interesting and useful. The replacement of the back component by a lens of greater focal length, increasing the focal length of the objective by about 50 per cent. we referred to some time ago, the alternative back lens being known as an "extension lens." Messrs. Taylor, Taylor and Hobson have now formulated a method by which the focal length may be reduced. This is effected by unscrewing the front component. One complete turn shortens the focal distance of a five-inch lens by nearly half an inch. Such a difference is of little use with reference to the resulting alteration in the scale of the image, though it may sometimes be convenient. But when applied as an alternative to the use of rack-work and other devices for increasing the distance between the lens and the plate for focussing purposes, as in the use of hand-cameras for comparatively near objects, this range is ample. Without moving either the objective as a whole or the plate, less than half a rotation of the front component of an objective of five inches focal length will alter the distance of the object that is in focus from infinity to three yards. The makers take advantage of this fact in a new issue of their lenses, in which a scale is engraved on the mount so that objects at infinity, ten, six, four and three yards' distance may be brought into focus by this simple means. Within this range the defining power of the objective from corner to corner of a quarter plate, using the full aperture of $f/6{\cdot}5$, is so little affected that the deterioration of the image at the edges of the plate can only be detected by means of a magnifier. The advantages of this method of focussing are that it is more simple from a constructional point of view than others now in use, saving the weight of those parts hitherto necessary simply for focussing purposes, and that as the lens and plate may be rigidly fixed in their relative positions, there is less risk of instability or misplacement with the consequent deterioration of definition. The same principle is applicable when the "extension lens" is employed, thus further increasing the range of adjustment possible.

MESSRS. R. FRIEDLANDER UND SOHN, of Berlin, have issued two catalogues of floras, one of European, the other of exotic plants.

ACCORDING to the Report for 1901, the Manchester Microscopical Society continues to do excellent work, although the hon. secretary has to deplore a diminished attendance at the meetings.

Nature Notes for July contains a notice of Mr. E. N. Buxton's efforts for the re-afforestation of a large part of the old Hainault Forest, which was deforested about 1850. The cost will be about 20,000*l*. for the Lambourne and Hainault lands, and 7000*l*. for the Grange Hill Forest. It is proposed to ask the great City Corporations and the Essex County Council to bear the main cost, although much financial help is expected from private beneficence and local bodies.

IN a paper published in vol. lxxi. of the *Journal* of the Asiatic Society of Bengal Mr. F. Finn notices certain instances of what he terms "abrupt variation" in Indian birds. Among them he notices a not uncommon colour-phase in the ruff, and for the birds displaying this peculiarity he proposes the name *Pavoncella pugnax leucoprora*; this, it may be mentioned, is not in accordance with modern practice, which restricts subspecific titles to local geographical forms. The author also calls attention to a domesticated cock in the Indian Museum, described many years ago by Blyth, which has partially assumed the female plumage, and appears to be the only known example, at least in India, of such an abnormality.

THE failure of pea crops forms one of the more important items in the *Bulletin* issued this year by the authorities of the agricultural experiment station at Fort Collins, Colorado. It was discovered that the soil was permeated with the hyphæ of a Rhizoctonia, similar to, if not identical with, that which is destructive to potatoes. Peas are more resistant to the attacks of this fungus than potatoes, but under certain conditions, such as in a heavy soil which holds the water and while the plants are young, the fungus gets the better of the struggle. In the case of seeds taken from diseased potato plants, treatment with solutions of corrosive sublimate or formalin has been found to prove efficacious, and probably this will also hold good for peas. A Rhizoctonia was also found to be the cause of disease on blackberries. Injurious effects of spraying apple trees with Bordeaux mixture are reported, causing malformation of the fruit. These and other pathological effects are illustrated by excellent plates produced from photographs.

CAPTAIN STANLEY S. FLOWER has issued his Report, for 1901, on the Zoological Gardens at Ghizeh, near Cairo, which are now placed under the Public Works Department of the Government of Egypt. The Report gives an excellent account of the condition and progress of this instituton, which seems to have prospered greatly under Captain Flower's directorship. The Gardens, which extend over about 50 acres, are beautifully treed and kept up; they are situated at Ghizeh on the left bank of the Nile, and are connected with Cairo by tramway. They contain living examples of about 700 species of mammals, birds and reptiles, and a great variety of plants. The number of visitors increases every year, and was 52,711 in 1901. The latest additions to the buildings are an elephant house, a lion house and a large aviary, besides other smaller structures. It is stated that examples of forty-five different species of wild birds were observed within the Gardens in 1901.

USEFUL suggestions for laying out, planting and cultivating a garden and grounds are given by Mr. T. W. Sanders in the second number of the series of rural handbooks in course of publication by Messrs. Dawbarn and Ward. Seven plans are given for laying out plots varying in area from a quarter of an acre to ten acres; and anyone free to follow the designs set forth, and capable of waiting patiently for the trees and shrubs to develop, may act with advantage upon the concise instructions which Mr. Sanders gives.

A CHEAP edition (price *6d.*) of Laing's "Modern Science and Modern Thought," revised and brought up to date, with a biographical note by Mr. Edward Clodd, has been issued for the Rationalist Press Association by Messrs. Watts and Co. With reference to the revision which the advance of knowledge during the last seventeen years has rendered necessary, Mr. Clodd remarks:—"The portions thus affected are those dealing with the continuity of Palæolithic and Neolithic man in Continental Europe; with the recent discovery of remains, probably of an intermediate form between man and ape, in Java; and with the remarkable discoveries in Babylonia, which appear to accord to that empire on earlier civilisation than that of Egypt."

MR. BENJAMIN KIDD is leaving England shortly for South Africa, in connection with studies on which he is engaged. Since the publication of "Principles of Western Civilisation" he has been occupied with articles of some length for the "Encyclopædia Britannica." One of these deals with the application of the doctrine of evolution to society. The article on sociology in the new edition will be contributed by Mr. Kidd.

THE question as to whether tellurium or iodine possesses the larger atomic weight has given rise to many researches since Mendeléeff pointed out that the conclusion drawn from the periodic system was opposed to the experimentally determined facts. This work has hitherto been principally devoted to tellurium, partly because as the rarer and lesser known element tellurium might possibly contain elements of higher atomic weight, but chiefly because the work of Stas in regard to iodine appeared so convincing that further determinations of this constant for iodine would be superfluous. Since all the work done on tellurium tends to show that its atomic weight is decidedly higher than that of iodine, Prof. Ladenburg has attacked the question from the other side, and has redetermined the atomic weight of iodine, using methods of purification differing from those adopted by Stas: the result is in almost absolute agreement with the usually accepted figure, so that the discrepancy between the conclusions of the periodic law and the results of experiment still remains unexplained.

THE current number of the *Berichte* contains a paper by Dr. W. Marckwald on polonium, the radioactive constituent of bismuth. The discoverers of these radioactive elements, M. and Mme. Curie, after numerous attempts to isolate this element, concluded that polonium is a species of active bismuth, and that there is as yet no proof that it contains a new element. Dr. Marckwald, after numerous fruitless experiments, has succeeded in obtaining a minute amount of polonium in a manner which would appear to exclude the possibility of its identity with bismuth. Starting with some kilograms of residues from pitchblende, about 1 per cent. of strongly radioactive bismuth oxychloride was obtained, and it was proved that this activity remained unchanged after several months. The acid solution of this was then treated with a stick of pure metallic bismuth, the metal becoming after some time coated with a black deposit. It was found that the activity of this deposit, as measured by the electroscope, far exceeded that of the original solution, the residual solution having lost its activity during the deposition. No deposit was seen when a second stick of bismuth was placed in this exhausted solution. The total weight of polonium obtained was only 5 milligrams, corresponding to an amount not exceeding 1 gram per ton of pitchblende. The author hopes to be able to obtain sufficient material to carry out an atomic weight determination.

ALTHOUGH the fact of the existence of a gaseous antimony hydride has been known for many years, it is only comparatively recently that it has been obtained in the pure state, and the accounts of the stability of the pure hydride differ considerably. Thus, according to Olszewski, who first succeeded in solidifying the gas, decomposition with separation of antimony occurs readily even at -90° C. The current number of the *Berichte* contains a paper on this subject by A. Stock and W. Doht. In order to obtain as rich a gas as possible, they made a careful study of the composition of the gas evolved from a series of alloys of antimony with zinc, sodium, calcium and magnesium, and they found that the magnesium alloy was much the best for the purpose. Thus, whilst the zinc-antimony alloys never yielded a gas containing more than 1 per cent. of the hydride, an alloy of one part of antimony with two of magnesium gave hydrogen containing from 10·4 to 14 per cent. of the antimony hydride. From this mixture the pure gas was easily solidified out with liquid air, melting at -88° C. and boiling at -17° C. The solid melts to a clear liquid, and evaporates without leaving any trace of antimony, and, in fact, the gas may be kept at the ordinary temperature for some hours before decomposition sets in.

THE additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Madame Delmas; two Ocelots (*Felis pardalis*), two Common Boas (*Boa constrictor*) from South America, presented by Captain W. H. Lacy; two Giraffes (*Giraffa camelopardalis*, ♂ ♀) from Kordofan, two Cheetahs (*Cynoelurus jubatus*), three Secretary Vultures (*Serpentarius reptilivorus*) from Africa, presented by Colonel Mahon; a Green Woodpecker (*Gecinus viridis*) British, presented by Mr. J. T. Jones; a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, presented by Miss Ina King; five Lions (young) (*Felis leo*), two Grévy's Zebras (*Equus grevyi*, ♀ ♀) from Southern Abyssinia, a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, five Pratincoles (*Glareola pratincola*), European, two Lesueur's Terrapins (*Malacoclemmys lesueuri*), two prickly Trionyx (*Trionyx spinifer*), an Alligator Terrapin (*Chelydra serpentina*) from North America, two Striated Snake-head Fish (*Ophiocephalus striatus*) from India, two Egyptian Geese (*Chenalopex aegyptiacus*) from Africa, deposited; an Ourang-Outang (*Simia satyrus*) from Borneo, two Golden-backed Woodpeckers (*Brachypternus aurantius*), an Indian Roller (*Coracias indica*) from India, two White-eyebrowed Guans (*Penelope superciliaris*) from South-east Brazil, purchased; a Duke of Bedford's Deer (*Cervus xanthopygius*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

BRIGHT METEOR OF JULY 13.—Several correspondents send particulars of a brilliant meteor observed over a wide area last Sunday evening, July 13, about 10.30. According to charts sent by Prof. F. J. Allen from Cambridge, and Mr. A. Macrae from Crouch End, the meteor, which was probably sporadic, first appeared at an altitude of about 40°, and travelling in a N.E.–S.W. direction crossed a line joining Jupiter and Markab at right angles, at about 25° from the former. The meteor travelled very quickly and was intensely bright. Prof. Allen says:—"It illuminated the landscape like a considerable flash of lightning, though the moon shone and incandescent lights were near." Its colour is given as "violet-white." Mr. C. Waterer, of Margate, also remarks:—"It lighted up the whole

landscape in a remarkable manner, and seemed to glow with a peculiarly steady light." Mr. C. G. Osborne, who saw the meteor at Godalming, says that the light was so brilliant that people in a large hall thought a flash of lightning had occurred.

The trail, which was about 10° long and lasted for 15–20 seconds, is described as being of a violet and blue colour, and before extinction it became quite sinuous.

The Rev. F. J. Jervis-Smith, who observed the meteor at Iffley, near Oxford, sends the following notes of his observation:—"Time, 10.30 p.m., July 13. Approximate angle subtended by total length of luminous path about 15°. Line of flight downwards and nearly vertical. Bearing E.S.E. Angle between its highest point and the horizon about 45°. Time of duration about $2\frac{1}{2}$ seconds."

Mr. Walter E. Besley, director of the meteoric section of the British Astronomical Association, states in the *Times* that the course of the meteor was from R.A. 311° and north declination 21° to R.A. $310\frac{1}{2}$° and north declination $16\frac{1}{2}$°.

Discoverer of Nova Persei.—At a meeting of the Société Astronomique held on July 4, M. Flammarion informed the members that it was one of their number, M. A. de Borissiak, a student at Kieff, who first observed Nova Persei. This observer recorded the Nova as being equal in magnitude to β Geminorum at 8 p.m. February 21, 1901 (Pulkowa time), and, taking into account the difference of longitude, this was about 8h. 40m. before Mr. Anderson discovered it.

The Russian Government has presented M. Borissiak with a special medal for this discovery (*Bulletin de la Société Astronomique de France*, July).

Nova Persei.—The fourth report (June 1902) of the Variable Star Section of the British Astronomical Association, is devoted to a memoir in which Colonel Markwick has gathered together all the observations of the members on the magnitude, colour, light curve and spectrum of Nova Persei. The memoir contains several maps and charts of the region about the Nova, some very good light curves compiled, from many observations, by Mr. J. E. Gore and a series of excellent photographs of the Nova itself obtained by Mr. Alex. Smith at Dalbeattie, using a $5\frac{1}{4}$-inch doublet at various foci, sometimes with full aperture and sometimes with only half (*i.e.* a semicircular) aperture.

Hong Kong Double Star Observations.—Nos. 3798–99 of the *Astronomische Nachrichten* are mainly devoted to the observations of 200 double stars made by Mr. W. Doberck at Hong Kong.

Mr. Doberck describes his instrument, which seems to be an ancient one, and shows how the somewhat necessarily large errors have been eliminated. He insists that observations of the same double star should be separated by fairly long intervals in order to render them quite independent of each other, and contends that stellar objects should always be designated by the initial and number of the discoverer, and not by any reference to a general catalogue.

Observations of the Variable Star χ^2 Cygni during 1899.—M. Blum publishes in the *Bulletin de la Société Astronomique de France* an account of the observations of this star made during 1899 by MM. Ed. de Perrot and P. Sella.

The two sets of results and the curves plotted therefrom show very fair agreement, and M. Sella deduces the following conclusions from them:—

(1) The star is visible to the naked eye 3 days before and 30 *days after* the theoretical times.

(2) It increases to maximum (4·7) very rapidly, viz. in 17 days, but decreases very slowly.

(3) There exists a second maximum (4·8) about 28 days after the first, a third maximum (5·0) 16 days later than the second, and a fourth maximum about 18 or 19 days later than the third. The respective dates of observation were May 10, June 7, June 23 and July 11–12.

The complete range of variability of this star is about 8 magnitudes.

Rotation of the Brighter Fixed Stars, as a whole, with respect to the Fainter Stars.—In No. 3800 of the *Astronomische Nachrichten*, Sir David Gill communicates a preliminary note on the apparent rotation of the brighter fixed stars, taken as a whole, in regard to the fainter fixed stars, taken as a whole.

After comparing the common data given in the Cape Catalogues of 1880 and 1900, Newcomb's Fundamental Catalogue for 1900, Taylor's and other catalogues, and carefully correlating and eliminating the personal errors therein, the author arrives at the conclusion that the remaining discrepancies can only be accounted for by supposing the above-mentioned rotation.

The author urges that the greatest care should be taken to eliminate all the errors in reducing plates for the Astrographic Chart, and suggests that the Repsold-Struve method for magnitude correction, described by Cohn in the *Astronomische Nachrichten*, No. 3766, should be used.

Photographic Magnitude of Stars.—In a note to the Paris Académie des Sciences, M. Prosper Henry points out the effect of the influence of magnitude in causing errors, small but effective, in the reduction of stellar negatives.

Dissatisfied with the final utility of the method proposed by Sir David Gill in the *Bulletin du Comité de la Carte du Ciel*, he proposes a method where duplicate images of the same region are obtained very near together on the same negative, the one with a very short exposure, the other with a long exposure, and then by means of a formula in which the only variables are n, g' and g, he finds the quantity $\frac{n}{g' - g}$, which is the variation of the scale for a difference of one magnitude in the scale of magnitudes adopted, $g' - g$ being the difference in magnitude between the images obtained by the two different exposures. One advantage of this method is that it is not necessary to reduce the coordinates of the plate to right ascension and declination, neither is it necessary to correct for refraction unless the two exposures were made very far apart, and at some distance from the meridian.

MARINE BIOLOGY IN WALES.

As announced last week, Mr. G. W. Duff Assheton-Smith, of Vaynol Park, Bangor, who has for many years taken a warm interest in the zoological department of the University College of North Wales, has offered a site to the College for a marine zoological station, on condition that the maintenance of the station when erected is assured. The fine zoological collection at the College bears ample testimony to Mr. Assheton-Smith's interest, as he has frequently enriched it with valuable specimens from his menagerie at Vaynol. The site spoken of is on the Menai Straits, about midway between Bangor and the suspension bridge. Sheltered and beautifully situated, it is from every point of view the best site in the locality on which to place such an institution. Besides giving the site with his rights to the foreshore, Mr. Assheton-Smith will also give the necessary facilities of access through his property. In the laboratory, aquarium and enclosures, which will be features of the station, investigations and experiments in connection with our fisheries will be instituted and carried out. The Menai Straits possess a peculiarly rich fauna, and material is always available for investigation and experimental purposes.

A brief note on the steps which have led up to this development may not be out of place. When, in 1892, the Liverpool Marine Biological Committee decided to vacate the station on Puffin Island and to take up its headquarters at Port Erin, Prof. Herdman offered, on behalf of his committee, to dispose of the Puffin Island station to Prof. White. Being unwilling to allow an institution of this nature so near to his college to lapse, and at the same time being desirous of continuing the work of the station as far as possible, Prof. White, with the cooperation of some of his colleagues, provided the money to acquire it. With the assistance of friends he also raised a small income for the maintenance of the building, for carrying on the work and for the publication of reports. A committee for investigating the fauna and flora of the coast of North Wales, and for promoting the sea fisheries, was formed and the work began. An account of the work accomplished is given in the various reports which have been issued.

The inaccessibility of the island, and other obvious difficulties connected with an isolated position, frequently presented themselves, and these led Prof. White to cast round for a more suitable situation, with the result as noted.

In addition to the promise of a site, the College obtains the professional services of an accomplished architect—Mr. Harold Hughes, of Bangor—free. Mr. Hughes took much interest in the Puffin Island station, and both he and Prof. White made some interesting excavations to elucidate the past history

of the island. A start has been made in raising the building fund, and Mr. Henry R. Davis, of Treborth, who acted as hon. treasurer of the Puffin Island station since 1892, has made a handsome contribution. It is hoped that his example will be largely followed.

With regard to maintenance, hopes are entertained that some money from Government sources will be available. A year ago the College approached the Board of Trade with a view of obtaining a grant to enable it to undertake systematic investigations in connection with fisheries, and recently the College put forward its claims for support before the Ichthyological Committee of the Board.

FORESTRY.

THE opening paper in the *Transactions* of the Royal Scottish Arboricultural Society, 1901 (vol. xvi. part iii.) is by Mr. J. S. Gamble, C I.E., F.R.S., and gives a full account of the Forestry Exhibition in Paris in 1900, in the "Palais de Forêts, de la Chasse et des Cueillettes," the latter term practically meaning productions of various kinds, from baskets and fishing-rods to sponges and Russian caviare. The chief exhibit by the French Government was a series of models, photographs, pamphlets, &c., on the reclamation of mountain sides, including a large diorama representing a hill-side before—and several years after—reclamation. All these illustrate the magnificent work done by France in the last forty years, during which nearly 640 square miles of country have been reafforested at a cost of about two and a half million pounds. Mr. Gamble refers to the necessity of such work being undertaken in the Himalayas, where landslips due to forest denudation have wrought wholesale destruction. He instances hill-slopes which he once knew as covered with fine forests, but which are now bare and scored with landslips, while their gentle streams have been converted into torrents. The "sufficient for the day" policy of Indian administrators constantly neglects the work of preserving mountain forests, which is done seriously and systematically and with the best results in France, Austria and Hungary. The possession of a world-wide empire should induce us also to undertake such an obvious duty. More has been done in India to fix shifting sands, chiefly by means of casuarina plantations along the Coromandel coast, here also following the great French work in Gascony, where 260 square miles have been reclaimed and planted with maritime pine. The Germans have also afforested nearly the whole North German coast with *Pinus sylvestris*.

A great feature of the International Sylvicultural Congress held at Paris during the progress of the Exhibition was M. Mélard's paper on the world's annual excess of imports over exports of timber, which he estimated at 3,437,115*l*. in 1898, the chief importing countries being Britain, showing an annual excess of imports over exports of 20,523,758*l*., and Germany, 13,741,240*l*., and the chief exporting ones Austria-Hungary, having an excess of exports over imports of 7,941,422*l*., Sweden, 7,927,080*l*., Russia, 5,361,285*l*., and Canada, 5,077,756*l*. Alluding to the enormous imports of timber into the British Isles, M. Mélard notes that we have annually to build houses, factories and workshops for an increased population of 300,000, more than equal to that of Bordeaux, the third town in France. The large imports of timber into Germany, where 26 per cent. of the country is forest, much of which is scientifically managed, is a remarkable proof of the recent great economic development of that country.

The second paper in the *Transactions* is a reprint of Dr. Schlich's lecture at the Society of Arts, London, on February 27, 1901, on the world's timber supply, which gives more recent figures than M. Mélard's. Dr. Schlich had broken ground on this subject in March, 1897, in a lecture at the Imperial Institute; in the present paper he gives very full statistics, and sums up with the statement that plenty of hard-wood is still available, but that coniferous wood (soft-wood), which forms 85 per cent. of the total demand, can be continuously provided only by Sweden, Russia and Canada. Sweden, where the forests are well managed, may be able to increase its yield to 1,500,000 tons, out of a total demand of about 9,000,000 tons of coniferous timber, but the Russian supply is precarious; the great stand-by for coniferous timber will be Canada, if the Dominion Government does not lose time in introducing a rational management of the Canadian forests.

There are two useful papers by Mr. R. C. Munro Ferguson, M.P., the first on the arboricultural adornment of towns, with a list, by Prof. Bayley Balfour, of the shrubs and trees flourishing in the Royal Botanic Garden, Edinburgh. It is not, says Prof. Balfour, the low temperature of Edinburgh that retards the growth of woody plants, but winds blowing during cold weather deprive the plants of their water, so that, given shelter, a large number of trees and shrubs may be grown. Mr Ferguson's second paper is entitled "Hints on the Training of Foresters." The advice given is excellent, and should be read by all young woodmen. Schools for woodmen might with advantage be established in the Crown woodlands adjoining the Forest of Dean and the New Forest, as well as near Edinburgh, but the great requisite for this country in forestry education is that it should be available at our universities, so that land owners, land agents and future colonial administrators may be taught the importance of forestry. At present it takes several years to teach a new colonial governor not to devastate woodlands, and as soon as he has learned the lesson and prepared a useful forest scheme he has to go, and his successor frequently upsets all he has done.

Several useful papers follow by different authors, chiefly estate woodmen, and in one of these, by Mr. D. A. Glen, on "Forestry in Kent and Sussex," the following passage occurs:—"In many of these woods, not only the dead leaves, but every bit of herbage and vegetable undergrowth is carefully raked together and carted away to make litter, which, after it has been well rotted in the cattle-sheds, is utilised as manure for the hop-fields." This practice is apparently also followed in Hampshire, and the future ruin of these impoverished woodlands is as certain as those treated similarly near Nuremberg, where the Scotch pine has become a dwarf tree rarely exceeding 12 feet in height.

Paper No. 41 of the *Transactions* is an account of a deputation last October to the President of the Board of Agriculture. This has been followed by the appointment by Mr. Hanbury of a Departmental Committee, "to inquire into and report as to the present position and future prospects of forestry, and the planting and management of woodlands in the United Kingdom, and to consider whether any further measures might with advantage be taken, either by the provision of further educational facilities, or otherwise, for their promotion and encouragement." Mr. Hanbury's committee is admirably selected, and the best results may be anticipated from its deliberations if only money is forthcoming to carry them out.

Colonel Bailey, R.E., the Instructor in Forestry at Edinburgh, gives some "Notes on the Forests of Norway," chiefly compiled from an official publication, which will be very useful to the members of the Royal Scottish Arboricultural Society in their proposed excursion to Norway this year. Last year's excursion was to woodlands near Glasgow, an account of which and several useful notes and queries on forest questions close this volume. The Society is to be congratulated on the excellent work done under its auspices.

While the Royal Scottish Arboricultural Society has been in existence for forty-eight years and contains more than 900 members, the English sister society is twenty years old and contained 513 members when the last volume of its transactions was published.

These transactions, in the first place, deal with last year's excursion to some interesting woodlands within easy reach of Peterborough. Then follow the two prize essays, to each of which a silver medal was awarded, the former by Mr. J. Price, on forest roads, with diagrams, a most useful paper, and the latter by Mr. A. Deane, of the Warrington Museum, giving descriptions of the structure of British woods, with beautiful reproductions of photographs of transverse sections of each species. Other interesting papers follow: "Arboreal Tunnellers" (leopard moth, hornet clearwing, goat moth and wood wasp), by Mr. C. Morley; and on an oak canker due to a species of Stereum, which the author considers to be new, and proposes to call *Stereum quercinum*, by Mr. M. C. Potter, Professor of Botany at the College of Science, Newcastle.

Sir Hugh Beevor contributes the financial history of a four-acre mixed plantation, calculating the rate of interest at 4 per cent., which Sir J. Hooker considers forestry should pay before it will attract attention from investors. The financial history of this plantation is summarised in the following statement, which is of sufficient general interest for reproduction in the pages of NATURE.

(1) INCOME.

Annual recurrent Income per acre:—

Sporting Rent	£0 7 0
	£0 7 0

(1) EXPENDITURE.

Annual recurrent Expenditure per acre:—

Tithe Rent Charge	£0 2 1

1901 Estimated Profit after paying balance due, £75 = £19 per acre.

PLANTING COST, £40; RENT, £1.

An account follows of some French forests near Valenciennes and Compiègne, the latter having been selected for this year's excursion of the Society. It is shown that the French coppice-with-standards of St. Amand, with a rotation of twenty-five years, produces a net annual revenue of £1 2*s*. 8*d*. per acre, and that the splendid State forest of Retz, with an area of 32,550 acres under beech and oak, produces a net annual revenue of 17*s*. 7*d*. per acre, with a rotation of 150 years. Dr. Somerville, of the Board of Agriculture, the President of the English Arboricultural Society, contributes a notice on Prof. Schwappach's report on Prussian experiments with forest trees. The results most interesting to us are those obtained with *Fraxinus americana*, which withstands inundations better than *Fraxinus excelsior*, and develops its foliage fourteen days later than the latter, thus escaping ordinary spring frosts. *Larix leptolepis*, the Japanese larch, is also said to resist insects and fungi better than the European larch, while it easily reproduces injured leaders.

A Forestry Society has just been started in Ireland, so that all parts of the British Isles are now enlisted in the cause.

W. R. FISHER.

RECENT DISCOVERIES IN CHINESE TURKESTAN.

DURING the last twelve years or so, the attention of scholars has been repeatedly arrested by remarkable discoveries of ancient Hindu manuscripts in Central Asia. In 1889, Lieutenant Bower found an ancient birch-bark manuscript in Kuchār, in the northern portion of Chinese Turkestan. This "Bower Manuscript" was at once recognised as the oldest Indian manuscript extant. In 1891 and 1892, M. Petrovsky, Imperial Consul-General of Russia at Kashgar, and the Rev. F. Weber, missionary in Leh, Ladakh, made no less important finds of old manuscripts in the region of Kashgar. Again, in 1897, the French traveller M. Dutreuil de Rhins found, in the vicinity of Khotan, some leaves of a very ancient birch-bark manuscript, in which M. Senart recognised fragments of a Prakrit version of the well-known Buddhist text, the Dhammapada. Meanwhile Dr. Hoernle, then principal of the Calcutta Madrasah, to whom we are indebted for a splendid edition of the "Bower Manuscript," had drawn the attention of the Government of India to the remarkable records of ancient Hindu civilisation to be found in Central Asia, and on his recommendation instructions were issued to the British officials in Kashgar and Ladakh concerning the acquisition of antiquities from Chinese Turkestan, and a "British Collection of Central-Asian Antiquities" was gradually formed at Calcutta.

But all these had been more or less casual discoveries, and as soon as it became known that European officials were ready to pay high prices for such antiquities, native "treasure-seekers" made it their business to ransack the ancient sites in the desert, not without damaging them, for manuscripts and other remains, and some of them were even unscrupulous enough to manufacture "old books" and sell them to Europeans as "antiques" unearthed in the desert. In these circumstances it became really a matter of urgency that systematic explorations, by some competent scholar, should at once be undertaken in these parts, all the more so as no part of Chinese Turkestan had ever been explored from an archæological point of view. No man could have been better fitted for this task than Dr. M. A. Stein, who, by his excellent topographical and archæological work in Kashmir and other parts of India, as well as by his scholarly edition and translation of the "Chronicles of the Kings of Kashmir," has shown that he combines the thoroughness and profound knowledge of the true scholar with the energy and hardiness, the practical experience and tact of the explorer. All students of India must feel thankful to the Indian Government for securing the services of such a man for the archæological and topographical exploration of Chinese Turkestan.

In June, 1900, Dr. Stein was placed by the Government of India on a year's special duty, for the purpose of exploring the southern portion of Chinese Turkestan and more especially the region of Khotan. A Chinese passport from the Tsung-li-Yâmen was obtained, authorising him to travel and make excavations in Chinese territory. The Survey of India Department rendered material assistance by deputing one of the sub-surveyors, Babu Ram Singh, to accompany Dr. Stein on his travels, and by providing the necessary equipment of surveying instruments. Thus Dr. Stein was enabled, throughout the whole of his journey, to carry on geographical work along with his most interesting archæological researches.

A "Preliminary Report,"[1] published by Dr. Stein shortly after the completion of his journey, gives information about the character and scope of his explorations and their principal

[1] "Preliminary Report on a Journey of Archæological and Topographical Exploration in Chinese Turkestan." By M. A. Stein, Indian Educational Service. Published under the authority of H.M.'s Secretary of State for India in Council. (London, 1901.)

results. As to the intrinsic historical value of the discoveries made there can be only one opinion. It is true their full import will only be realised after the publication of the detailed report to be expected from Dr. Stein himself, and after a thorough examination of the archæological specimens, photographs, coins and manuscripts which will occupy scholars for many years to come; but even a perusal of the "Preliminary Report," and a glance at the illustrations and plates added to it, suffice to show that they will shed a flood of light on the history of an important period, and on the manifold relations between India and Central Asia during the first centuries of our era.

Dr. Stein left Srinagar on May 29. He travelled by the Gilgit-Hunza route, and on June 28 crossed the Kilik Pass and entered Chinese territory on the Tāghdumbāsh Pāmīr. A five days' journey down the valley of this Pāmīr brought him to Tāshkurghān, the chief place of the Sarīkol mountain tract. Marching down the plains of Kashgar, he arrived, on July 29, safely at the capital of Chinese Turkestan. In Kashgar he made the necessary preparations for his travels in the desert, not only by organising a fresh caravan, but also by making efforts to secure the good-will of the Chinese authorities for the intended explorations. In these efforts he was assisted, not only by Mr. Macartney, the diplomatic agent of the Government of India at Kashgar, but also by—the famous Chinese pilgrim of the seventh century, Hiuen-Tsiang. "All educated Chinese officials," writes Dr. Stein, "seem to have read or heard legendary accounts of the famous Chinese pilgrim's visit to the Buddhist kingdoms of the 'Western countries.' In my intercourse with them I never appealed in vain to the memory of the 'great monk of the T'ang dynasty' (T'ang-Sên), whose footsteps I was now endeavouring to trace in Turkestan, as I had done before in more than one part of India."

On September 11, Dr. Stein left Kashgar and started on his journey to Khotan, choosing for his march to Yarkand, not the ordinary caravan route, but a track leading through the desert. After a short halt in Yarkand, he proceeded on the caravan route leading to Khotan along the southern edge of the desert, following "the same great thoroughfare by which in earlier times the trade from the Oxus region and the far West passed to Khotan and to China." A peculiar feature of this route and of the desert around Khotan are the "Tatis," as the natives call the "extensive patches of ground where the eroded loess is thickly strewn with fragments of coarse pottery, bricks, slag, and similar refuse marking the sites of villages and hamlets long ago abandoned"—an ideal marching ground for the archæological explorer. He reached Khotan town on October 12. The next four weeks were devoted to geographical work in the Kuen-luen range and Khotan mountains, whereupon he turned again to archæological interests, paying a visit to the Kohmārī ridge opposite to the village of Ujat, and examining old sites in the Khotan oasis, more especially those near the village of Yōtkan, where "treasure-seeking" has long been carried on along with jade-digging and gold-washing. Having finished the survey of ancient localities within the oasis, he started on December 7 on his way to Dandān-Uiliq, the site chosen for the first excavations in the Taklamakān desert. Marching through the desert, the small caravan, including a party of thirty labourers for the excavation work, found itself on December 18 in the midst of the scattered ruins of Dandān-Uiliq. This ruined site had been seen by Dr. Sven Hedin on his march to the Keriya Daryā, and is spoken of in the narrative of his travels as "the ancient city of Taklamakān." For fully three weeks most successful excavations were carried on by Dr. Stein amongst these ruins. On January 6, 1901, he left this neighbourhood, and marched across sand dunes, rising to a height of about 200 feet, to the Keriya Daryā, and along the hard frozen river to the oasis and town of Keriya, in order to secure the assistance of the Amban (the Chinese district magistrate) for his further explorations. Making inquiries at Keriya about old localities, he heard of an "old town" in the desert north of the Muhammadan pilgrimage place of Imām Jafar Sādīk. He set out in search of this ancient site, and reached Niya—the Ni-jang town of Hiuen-Tsiang—on January 21. Six days later he was among the ruins of the Niya River site, as Dr. Stein, in absence of any special local designation, calls this site, where the excavations, carried on for nearly three weeks, yielded the most important results of the whole journey. At Niya he had heard of old remains to be found in the desert to the east towards Cherchen, and he set out in search of them. Marching more than a hundred miles to the east from Imām Jafar Sādīk, he reached the point where the Endere stream is lost in the sands. A day's march further to the south-east brought him to the "old town of Endere," which was next explored. Interesting archæological remains and manuscripts were brought to light by the excavations. Some Tibetan manuscripts found here showed that the easternmost point of the exploration area had been reached. Hence Dr. Stein began to march back to Keriya and Khotan. Some 150 miles north of Keriya the ruins of Karadong—as they are called by the nomadic shepherds grazing along the Keriya Daryā—were visited and explored by Dr. Stein, before he continued his march to Khotan. The sandstorms and increasing heat warned him that work in the desert would soon become impossible. He hastened, therefore, to visit the ancient sites to the north-east of Khotan which had still to be explored. After examining the scanty ruins of Ak-sipil, some fifteen miles from the right bank of the Yurung-Kāsh opposite Khotan, he marched due north through the sands for about fourteen miles, when he reached the ancient site called Rawak by native "treasure-seekers." Here the last, but by no means the least interesting, excavations were carried on for a whole week. On April 18 the work was finished, and, having completed the programme of his explorations in the desert, Dr. Stein could return to the town of Khotan, where he arranged and carefully repacked his archæological finds. On May 1 he set out for Kashgar, where he made arrangements for his journey to Europe. He left Kashgar on May 29, and travelling through Russian Turkestan he reached, at Andijan, the terminus of the Transcaspian Railway. By it he travelled to Krasnovodsk, crossed the Caspian to Baku, and finally, on July 2, arrived in London, where he was able to deposit his important collection—twelve large boxes, containing numerous relievos, frescoes, painted tablets, and other specimens of Central Asian art, coins, manuscripts, and more than 800 negatives on glass plates, the photographic results of his journey—in the British Museum. A three months' period of deputation in London had to suffice for the provisional arrangement and cataloguing of his precious finds and for preparing the "Preliminary Report."

It would require far more space than I could be allowed in these columns to mention only the most important results of Dr. Stein's explorations. I must content myself with just pointing out the most striking features of the discoveries recorded in the "Preliminary Report." Though archæology and historical topography were the chief interests, and the desert around Khotan was the principal area of the explorations made by Dr. Stein, he missed no opportunity, throughout the whole of his journey, to attend to general geographical work as well and to make valuable anthropological and ethnographical observations.

Thus, in the interests of geography, he superintended the survey on the Tāghdumbāsh Pāmīr and in the Sarīkol mountain tract; and by choosing for his march to Kashgar the route which passes through the valleys between the Russian Pāmīrs and the western slopes of the Muztāgh-Ata range, he was able to extend this survey to the Muztāgh-Ata and the mountain ranges overlooking the Little Karakul Lake. Again, on his march from Kashgar to Yarkand he succeeded in fixing the position of Ordam Pādshāh more accurately than is done on the existing maps. After his arrival in Khotan he devoted a whole month to survey operations in the Kuen-luen mountain range, especially in that portion of it which contains the head-waters of the Yurung-Kāsh River. He also explored the hitherto unknown mountain tract towards the Karakāsh River and was able to complete the triangulation of the Khotan Mountains.

Anthropometric observations were made by Dr. Stein in all regions offering any anthropo-geographical interest, for instance among the Iranian hillmen in the Sarīkol settlements. Nor did he omit to make notes of any popular legends and folklore connected with interesting localities, and often he found "old stories" which Hiuen-Tsiang had heard and recorded in the account of his travels, still alive among the population. The tenacity with which local legends survive proved often very useful in the identification of old sites. Thus, near the frontier of the Khotan district, there is a Muhammadan shrine known as Kaptar-Mazar, *i.e.* "the pigeon's shrine," at which thousands of pigeons are kept and propitiated by food offerings, and a legend is told of a great victory won with the help of pigeons by some Muhammadan hero over a host of Khotan unbelievers. Now Hiuen-Tsiang tells us that some thirty miles to the west of the capital of Khotan there was a range of hills supposed to have been formed by the burrowing of rats, the rats having been

worshipped there owing to the popular belief that in ancient Buddhist times they had saved the land by destroying the leather of the harness and armour of some hostile army. The locality indicated by the Chinese pilgrim corresponds exactly to Kaptar-Mazar, and Dr. Stein has no doubts that the pigeons of the Muhammadan legend have taken the place of the rats of the legend as related by Hiuen-Tsiang.

During the whole of his journey, Dr. Stein paid the greatest attention to historical topography. Everywhere he tried to trace and identify ancient sites mentioned by Hiuen-Tsiang and other Chinese travellers. Thus—to mention only some of the more important results—Paloyo, the Dard designation of the people of Baltistān, was identified with the term Po-liu, as used in the Chinese Annals and in the narratives of the Chinese pilgrims. Sir Henry Yule's identification of Sarīkol with the K'ie-p'an-to territory of Hiuen-Tsiang was fully confirmed by Dr. Stein's investigations. On his march to Khotan he was able to identify the small oasis of Mōji with the town of Po-Kia-i, where a famous Buddha statue brought from Kashmir was worshipped in the times of Hiuen-Tsiang. Following the road once used by the Chinese pilgrim, he traced other ancient sites near the oasis of Zangūya, and close to the frontier of the Khotan district. Two identifications, previously made by M. Grenard, were fully borne out by the evidence found by Dr. Stein—that of the Kohmārī ridge and cave with the ancient Gośṛṅga mountain and the cave where the popular legend of Hiuen-Tsiang's time supposed a Buddhist saint to reside "plunged in ecstasy and awaiting the coming of Maitreya Buddha"; and that of the village of Yōtkan with the ancient capital of Khotan. Among the many proofs for the latter identification, the most convincing was that, from this starting point, Dr. Stein was able to identify the positions of the most important Buddhist shrines visited by Hiuen-Tsiang, the places of which are generally occupied now by Muhammadan Ziārats. Thus, the small hamlet of Somiya was found to correspond exactly to the Buddhist convent described by the Chinese pilgrim under the name of Sa-mo-joh. Finally, we may mention that on his march from the Karadong ruins to Keriya, Dr. Stein identified the position of the town of Pi-mo, described by Hiuen-Tsiang, in the neighbourhood of Lachim-Ata Mazar.

But it is chiefly for his archæological discoveries and his manuscript finds that Dr. Stein's journey of exploration will ever be memorable. We cannot enter here into details about the many interesting Buddhist monuments examined by Dr. Stein in the course of his travels in Gilgit, Hunza, Sarīkol and Kashgar, and the antiquities collected by him on the Yarkand-Khotan route, in Khotan town and in the village of Yōtkan. Also for the excavations made at the Endere site, at Karadong and at Ak-sipil we must refer the reader to Dr. Stein's "Preliminary Report." But a word or two must be said about the most important results of the excavations carried on among the ruins of Dandān-Uiliq, the Niya River site and of Rawak.

No less than fourteen detached temples and dwelling-houses were excavated in Dandān-Uiliq. First of all two temple cellas were brought to light, richly decorated with wall paintings and stucco images. The interior of the larger cella was occupied by a colossal stucco statue, probably representing a Buddha. Each of the four corners of the same cella was occupied by a draped stucco figure standing on a lotus-shaped pedestal. The cella walls were decorated, inside with frescoes showing figures of Buddhas or Buddhist saints, and outside with fresco bands containing small representations of saints, seated in an attitude of meditation. In style of composition and the drawing of figures, these wall decorations are similar to the later of the Ajanta frescoes. But as we possess only very few specimens of old Indian painting, the study of the Dandān-Uiliq frescoes will prove of particular interest. For the same reason, the small painted tablets which Dr. Stein discovered on excavating the temple cellas are of importance. They were probably votive offerings from worshippers who had come to visit the shrines in ancient times. A figure represented on one of these tablets shows the head of a rat—which is interesting in view of the legend of sacred rats mentioned above. Near the excavated buildings Dr. Stein generally found groups of shrivelled and bleached trunks of poplar and fruit trees, the remains of ancient orchards or avenues. Also traces of old irrigation channels were recognisable in the sand.

Of the manuscripts excavated at Dandān-Uiliq, the most important are some oblong leaves of paper inscribed with old Indian Brāhmī characters (*i.e.* the alphabet which is written from left to right, and used in the edicts of King Asoka, and similar epigraphic documents), and belonging to five different manuscripts, three of which are in Sanskrit and contain Buddhist texts. From their palæographic peculiarities Dr. Stein concludes that they cannot be later than the seventh, and may belong even to the sixth or fifth, century. Moreover, there were found single leaves of thin, coarse paper, inscribed with cursive Indian characters, but showing a non-Indian language, and some Chinese documents of similar material and appearance. Two of the latter bear dates, according to which they must have been written between 763–805 A.D. Dr. Stein thinks that these dates indicate about the time when the dwellings were abandoned. The evidence of numerous coins found in the course of excavations supports this dating of the Dandān-Uiliq ruins.

Among the most interesting discoveries in the ruins at the Niya River site, there are remains of two large dwelling-houses, excavated by Dr. Stein. In one of them some specimens of household furniture, illustrating the industrial arts of the period, were found, amongst others a wooden chair with ornamental wood carving, the decorative motives of which closely resemble those of the relievo sculptures of the Buddhist monasteries of Yusufzai and Swat (the ancient Gandhāra). In one room, the stuccoed walls of which showed a carefully executed fresco decoration, the pieces of a coloured rug—an interesting specimen of ancient textile industry—were brought to light. Again, in another of the excavated houses there were found the legs and arm-rests of a wooden chair, representing lions and human-headed monsters, and still retaining traces of colour, and also the broken end of a kind of guitar, resembling the popular "Rahāb" of modern Turkestan.

But most important of all are the manuscripts unearthed at the Niya River site. More than 500 wooden tablets inscribed with ancient Kharoshthī characters (*i.e.* the alphabet written from right to left, and known chiefly from Indo-Scythian and Indo-Greek coins, found in the north-west of India) were found among the ruins of this site. Most of them are wedge-shaped, from 7 to 15 inches long, and arranged in pairs; and some of them still retained their string and clay sealing intact, thus illustrating the ingenious manner adopted for the fastening and sealing of these documents. Other tablets were oblong, some of considerable length (up to 30 inches), resembling the Indian palm-leaf manuscripts. An ancient pen, made of tamarisk wood, with a bone knob, was found, and gives us some idea of clerical work in this remote period. A considerable number of these tablets were found in an ancient rubbish heap, and there were also some narrow pieces of wood inscribed with Chinese characters. The same rubbish heap yielded another very rare, and in a Buddhist country particularly surprising, writing material, namely, about two dozen documents written in Indian Kharoshthī characters on leather. A thorough examination of all these documents as to their contents will take much more time than Dr. Stein was able to bestow on them during his short deputation. But he could make out that most of them were written in an old Prakrit dialect with an admixture of Sanskrit terms, and the wedge-shaped tablets seem to contain correspondence, records of agreement, bonds, memoranda and the like, while religious texts, votive records, &c., will probably be found to form the contents of the longer tablets. As to the date of these documents, palæographical evidence proves them to belong to the first centuries of our era. For the writing resembles closely that on the inscriptions of the Indo-Scythian kings who ruled over the Punjab and the Kabul region during the first two centuries, and the Kharoshthī alphabet soon ceased to be used after that period. These wooden tablets must, therefore, be considered at present as the oldest Indian manuscripts extant. The use of wood as writing material is also a proof of considerable antiquity. From the fourth century onward, the use of paper as writing material is attested for Turkestan. Yet not the smallest scrap of paper was discovered in the ruins of the Niya River site. Numismatic finds, as well as the influence of classical art shown on some of the clay seals attached to the tablets, confirm this dating.

The last excavations were those made at Rawak, where Dr. Stein found an imposing Stūpa surrounded by a court forming a quadrangle 164 feet long and 143 feet broad. Both inside and outside, the walls of this Stūpa court were decorated with rows of colossal statues in stucco, representing Buddhas or Bodhisattvas, and between them at frequent intervals with smaller relievos

representing deities and saints. The whole of the relievo work had originally been coloured, and there were fresco paintings besides. The excavations of these relievos proved no easy task, as the structures threatened to collapse when the sand was removed. Yet Dr. Stein succeeded in clearing ninety-one large and numerous small relievos. Photos were taken of the larger relievos, while the smaller ones were taken to England. In style and details of execution the Rawak sculptures resemble the Græco-Buddhist sculptures of the Peshawar Valley and the neighbouring regions. Chinese copper coins, found among the ruins, proved to be coins of the Han dynasty. As the rule of the kings of this dynasty covers the period of 25–220 A.D., and some of their coins are known to have been current until the close of the fourth century, we have thus a chronological limit, to which the Rawak sculptures may safely be referred.

Finally, we must at least touch upon one negative, though none the less important, result of Dr. Stein's journey of exploration. During his last eight days' stay at Khotan he succeeded in clearing up the doubts he had long entertained concerning the genuineness of certain very puzzling manuscripts and blockprints "in unknown characters" which had for some years past been purchased from Khotan and added to the "British Collection of Central-Asian Antiquities" in Calcutta. With the help of the Chinese authorities he got hold of the very man—one Islām Ākhūn—from whom most of these documents had been bought. The man was brought before Dr. Stein, who forced from him, in the course of a prolonged cross-examination, an open confession of his manufacture of "old books." Dr. Stein has shown that it is easy to distinguish the forgeries from genuine old manuscripts, and there is no fear that any scholar will, in future, be deceived into trying to decipher the "unknown characters" of Khotan manuscripts.

This brief sketch will suffice to give an idea of the singular importance of the discoveries made by Dr. Stein. But the costly treasures brought by him from Chinese Turkestan will require the most careful examination and study to be made fruitful for further research, and who could be better fitted for this task than the happy discoverer himself? While congratulating both the Indian Government and Dr. Stein on the brilliant discoveries made in Central Asia, we can only express our sincerest hope that the authorities of the India Office may see their way to grant Dr. Stein the leisure required for completing the work so happily begun, in order that the present "Preliminary Report" may soon be followed by a Detailed Report of Dr. Stein's tried workmanship.

M. WINTERNITZ.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE authorities of Reading College have received an intimation that the Treasury recommends the advancement of the College to the list of University Colleges, with a Government grant of 1000*l.* a year for five years. The grant will be subject to the Treasury audit, but local subscribers have assured the necessary income.

PROF. HEWLETT, director of the Department of General Pathology and Bacteriology at King's College, London, has arranged a vacation course in practical and clinical bacteriology to commence Wednesday, August 6, and end Saturday, August 16. The course will consist of lectures, demonstrations and practical work; in the latter, the members of the class will make for themselves permanent preparations of the cbief pathogenic micro-organisms and will carry out the principal manipulations employed in bacteriological investigations.

A MEETING of numerous representatives of primary, secondary (including technical) and other branches of education was recently held at the Municipal School of Technology, Manchester, to consider whether arrangements should be made for a conference of science teachers in the north of England on the lines of those established by the Technical Education Board of the London County Council, which have been held in London during the Christmas vacation for some years past. The proposal to hold similar conferences in the north of England was unanimously adopted, and a committee formed to make the necessary arrangements. The first conference will be held on Friday and Saturday, January 2 and 3, 1903, at Manchester.

A LIST of requirements and courses at the Clarkson Memorial School of Technology, Potsdam, New York State, has been received. The institution was founded in 1895 to provide technological education of college standard, and is a constituent college of the University of the State of New York. It is of interest to note that the regular courses of work extend over four years and that satisfactory evidence of thorough preparation must be given by students who wish to enter the college. Now that the London polytechnics are part of the University of London, efforts should be made to introduce or extend the same kind of regulations as to systematic work and preliminary studies.

HITHERTO none of the technical institutes has been specially organised for the optical trades, though optical classes have been held in several of them, notably in the Northampton Institute in Clerkenwell. But the optical trades appear to have awakened to the need of specialised instruction of the highest kind for the young men in their industry, and a movement to create a real Optical Institute is on foot. The Optical Society has approached the Technical Education Board of the London County Council to urge upon it the creation of such an establishment. If the Techn ical Education Board could see its way to organise and equip a special technical school in optics, and endow it with a grant of 3000*l.* or 4000*l.* a year, we might expect great things for the future of the optical trades. When it is remembered how greatly the electrical industries of Great Britain have benefited by the electrical teaching and the electrical laboratories established twenty years ago by the City and Guilds Institute, one wonders why similar optical laboratories, properly equipped for the teaching of technical optics, have not been long ago organised. The present movement is a sign that England is waking up.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 13.—"The Refractive Indices of Fluorite, Quartz and Calcite." By J. William Gifford. Communicated by Prof. Silvanus P. Thompson, F.R.S.

Tables are given of the refractive indices of the above substances for twenty-six wave-lengths, from wave-length 7950 Rb to wave-length 1852 Al inclusive at 15° C., and of the temperature refraction coefficients. To ensure accuracy a new method of observation was adopted. The prisms were polished on three sides, and deviations were measured at each of the three angles. The indices were calculated by the formula

$$\mu = \sin \tfrac{1}{2}(D + 60°)/\sin 30°.$$

The difference of the angles of the prisms from 60° were in each case less than 4 seconds of arc. When this is the case the error introduced is less than 0·0000001 in the index. It is not, therefore, necessary to measure the angles with accuracy. Some of the rays from the collimator are reflected from the base of the prism and enter the telescope. The image of the slit thus obtained coincides with the refracted image only when minimum deviation is reached. In cutting the goniometer circle a burr is thrown up by the engraving tool on each side of every division. By two small electric lamps behind the reading microscope either or both burrs are made to appear as fine white lines. With the help of quartz fibres measurements are made on these and the mean taken. A correction is made for the error of the reading microscope, and special precautions have been taken to ensure the optical correctness of the prisms. An exact copy of the original measurements for line C fluorite is given. An approximate estimate of the total error gave for the 119 indices in the table,

33 less than... ...	0·0000023
39 ,, ...	0·0000034
31 ,, ...	0·0000084
15 more than ...	0·0000084
1 only as great as but not more than ...	0·0000150

Some indices for left-handed quartz are given, and a rough determination of the specific gravities of right and left quartz. The partial and proportional dispersions of fluorite, quartz and calcite for the visual spectrum and their lens combinations are also given, together with a list of focal lengths for unity and a table of curves for the whole spectrum with ordinates for a mean focal length of six thousand nine hundred and eighty-five millimetres.

PARIS.

Academy of Sciences, July 7.—M. Bouquet de la Grye in the chair.—The president announced to the Academy the loss it had sustained by the death of M. Faye, member of the Section of Astronomy.—On the relation between the intensity of the voltaic current and the amount of electrolytic action, by M. Berthelot.—The properties of a certain anomaly capable of replacing the anomalies already known in the calculation of the disturbances of the smaller planets, by M. O. Callandreau.—On the development of analytical functions in a series of polynomials, by M. Paul Painlevé.—The local treatment of the localisations of rheumatism, by M. Ch. Bouchard. From the experimental results quoted, the superiority of local treatment by injection over general treatment by the same drug (sodium salicylate) is well marked. The author concludes that in general it is better to apply the drug only at the place where it is useful, by injection.—M. Bouvier was nominated a member of the Section of Anatomy and Zoology in the place of the late M. Filhol.—On a new linear group of four variables, of finite order, by M. Léon Autonne.—On the electrolysis of silver nitrate, by M. A. Leduc. It is generally stated that the bath of nitrate of silver becomes more and more acid after prolonged electrolysis; the contrary effect was, however, observed by Rodger and Watson. It is shown how either result may be obtained by varying the conditions in a definite manner. It is noted incidentally that the counter electromotive force of a silver nitrate voltameter, which has been usually assumed to be zero or extremely small, is in reality by no means negligible, amounting to about 0·03 volt.—On the action of self-induction in the ultra-violet portion of spark spectra, by M. Eugène Néculcéa. A continuation of previous papers, the present instalment giving a study of tin.—New researches on open currents, by M. V. Crémieu.—On the nature of the coherer, by M. J. Fenyi. A coherer formed of four steel needles in parallel is no more sensitive than a single needle, but if the four are placed in series a greater electromotive force can be placed in the circuit, and the sensibility is accordingly increased.—The dissociating action of the divers regions of the spectrum on matter, by M. Gustave le Bon.—Dark light and actinoelectric phenomena, by M. Gustave le Bon.—On the hydration of zinc oxide, by M. de Forcrand. A thermochemical study of the solution of zinc oxide.—The oxidising properties of a pyranol, by M. R. Fosse. Dinaphthopyranol possesses an oxidising action towards hydriodic acid, an attempt to prepare the hypoiodite resulting in the formation of the tri-iodide of the oxonium compound.—The condensation of nitromethane with aromatic aldehydes, by MM. L. Bouveault and A. Wahl. The best condensing agent for the reaction between the nitromethane and the aromatic aldehyde is sodium methylate; the sodium salt which separates is then treated with zinc chloride. The reaction has been applied to anisic, piperonylic and ortho-nitrobenzoic aldehydes and to furfurol.—The action of diazoic salts on desmotroposantonine and desmotroposantonous acid, by MM. E. Wedekind and Oscar Schmidt.—On a new proof of the cellular resistance of the saccharomyces and on a new application of this property to industry and the distillery, by M. Henri Alliot. The method which is usual in distilleries for removing nitric acid and other volatile acids prejudicial to the development of the yeast is to add sulphuric acid to the molasses, heat to boiling and force through a current of air. To avoid this, the author takes some of these volatile compounds and grows an acclimatised yeast by gradually adding increasing quantities of these antiseptic compounds to the cultures. The properties thus acquired by the yeast are sufficiently permanent for industrial use in the distillery.—On the active principles of the poison of the toad, *Bufo vulgaris*, by MM. C. Phisalix and Gab. Bertrand. Toad poison owes its activity to two principal substances—bufotaline, of a resinoid nature, and bufotenine.—On the nature of bufonine, by M. Gabriel Bertrand. The bufonine described by Faust does not exist in toad poison directly extracted from the glands, but has its origin in other parts of the skin. It appears to be an impure cholesterine.—The influence of sulphocyanic acid on the growth of *Aspergillus niger*, by M. A. Fernbach. The sulphocyanide does not appear to interfere with the growth of the mycelium, but arrests fructification.—On the influence of choline on the glandular secretions, by M. A. Desgrez. Although an advanced decomposition product of albumin, choline is not without use to the organism in which it is produced, it exerts a favourable influence on the nutritive exchanges and contributes especially to the retention of phosphorus.—The disappearance of ethers in the blood *in vitro*, by MM. Maurice Doyon and Albert Morel.—Inhibition produced by interference on the retina, by M. Aug. Charpentier.—On the autoregulation by carbonic acid of the energetic working of organisms, by M. Raphael Dubois.—The influence of temperature on the parthenogenetic development, by M. C. Viguier.—On the evolution of the branchial formations in the lizard and slow-worm, by MM. Prenant and Saint-Remy.—Contributions to the anatomical study of *Rhabdopleura Normani*, by MM. A. Conte and C. Vaney.—On the cause of the changing colours of teguments, by M. H. Mandoul.—On a new method for the destruction of the pyralis and other noxious insects, by MM. Vermorel and Gastine. The use of liquid insecticides having proved non-efficacious, recourse was had to gaseous poisons, hydrocyanic and sulphurous acids, sulphuretted hydrogen, &c., but without effect. By means of a special apparatus, steam at 50° C. was then applied to the leaves, and this mechanical method, which used with due care proved to be without injurious effects on the vines, was found to be very serviceable.—On the presence of the Aptian stage in south-east Africa, by M. W. Kilian.—On the volcanic eruption of May 8 at Martinique, by M. Thierry.

CONTENTS.

THURSDAY, JULY 24, 1902.

THE ENCYCLOPÆDIA BRITANNICA.

The Encyclopaedia Britannica. Vol. xxvi. Aus.-Chi. (Vol. ii. of the tenth edition). Pp. xxii + 763. (London and Edinburgh: Adam and Charles Black; and The *Times*, Printing House Square, London, 1902.)

SEVERAL articles of scientific interest are contained in this volume, but limitations of space will only permit us to refer to a few of them. Among the subjects of contributions, in addition to those mentioned below, are Balanoglossus, by Dr. A. Willey; George Bentham, by Sir William T. Thiselton-Dyer; Birds, by Dr. H. Gadow; Brachiopoda, by Mr. A. E. Shipley; Calibration and Calorimetry, by Prof. H. L. Callendar; and the Channel Tunnel, by Prof. Boyd Dawkins. There are also articles on all geographical divisions having names between Austria and Chicacole.

The subject-matter of the article on "Bacteriology" has been divided into two sections, general and pathological, the former of which has been contributed by Prof. Marshall Ward. Commencing with a brief introduction upon the botanical position and affinities of the Schizomycetes, their general morphology, structure, flagellation and sporulation are then considered, the difficulties of classifying them discussed, and an outline of Fischer's system of classification detailed. The life and functions of the various classes of bacteria are next dealt with, and a brief, but sufficient, account is given of their growth, action of physical agents upon them, and of the nitrifying, cellulose, sulphur, pigment, phosphorescent and other forms, of the various fermentations, and of symbiosis. The effects of light upon bacteria are described, but we are inclined to think that the author lays too much stress upon this agent as a factor in the bacterial purification of streams, &c.; nor is it at all certain that the cure of lupus effected by the "light" treatment is due to the bactericidal action of the light rays.

In dealing with the bacteriosis of plants, it is pointed out that the evidence of the bacterial invasion of vegetable tissues must be accepted with caution and be carefully controlled, as in the majority of instances the bacteria are secondary, and have gained access along the dead hyphæ of an invading fungus or through the punctures due to aphides or other insects.

Not the least interesting and instructive portion of this article is the brief discussion of the possible sources of energy which contribute to the wonderful activities exhibited by these minute organisms.

The whole of this section, while showing a wide and comprehensive grasp of the subject, is a model of conciseness, and its value is enhanced by several original illustrations.

The pathological section is from the pen of Prof. Muir, and, after an historical introduction, the methods employed for the study of the bacteria are summarised. The general features of infection are then considered, and the nature of toxins, disease-production, susceptibility and immunity are briefly, but sufficiently, discussed; in fact, we have been unable to note any omission of importance.

The formation of antitoxin and the nature of the antagonism between antitoxin and toxin are next considered, and this leads naturally to an exposition of Ehrlich's "side-chain" theory, which is clearly described. Lastly, the nature of anti-microbic sera and the phenomena of bacteriolysis, of agglutination and of phagocytosis are considered, and another admirable survey is concluded with a few critical remarks upon natural immunity.

In the article upon "Brewing," by Dr. Schidrowitz, the reader is presented with an able summary of modern practice in this important industry, and much additional information is given, statistical and legal, and upon such subjects as the cultivation of barley for malt, malt and malting, hops, and malt and hop substitutes. The process of mashing and the changes which ensue, fermentation and the practical application of Hansen's discoveries, and brewing with pure cultures are briefly described. The article seems to be well up to date; for example, Buchner's yeast-cell extract or "zymase" and the theories respecting its nature are mentioned.

Beri-beri, that remarkable disease having the characters of a multiple peripheral neuritis, is described by Dr. Shadwell, his description, however, being mainly based upon Manson's writings (referred to, by the way, as Sir Patrick; may it be an omen). Ross's suggestion that beri-beri is a form of arsenical poisoning is alluded to, but is not considered probable. The micro-organisms of Pekelharing and Winkler and of Rost are not mentioned, and the absence of fever in the disease does not necessarily exclude a micro-parasite, as is suggested.

The article on cancer, also from the pen of Dr. Shadwell, deals mainly with the statistical problems presented by this dread disease; the pathological ones, we understand, will be discussed in another place. With regard to the alleged increase of cancer, it is considered that

"on the whole it must be held that though there has probably been some increase, it has not been satisfactorily proved and is certainly less than is supposed."

R. T. H.

The supplementary article on chemistry contributed by Prof. Armstrong fills thirty-eight pages and surveys almost the whole field of scientific chemistry. The task of reviewing the article is such that I have felt inclined to shirk it altogether; for the article proves to be, not so much a record of recent advances in chemistry as a manifesto of Prof. Armstrong's own views on the chief phenomena and problems of modern chemistry. With these views I am entirely out of sympathy. I should be willing enough to say why, but I should want nearly as many pages to traverse Prof. Armstrong's statements as he has occupied in making them. I can do no more than give one or two examples of my meaning.

At the outset of the article we have a reproduction of the table of the elements which Prof. Armstrong recently brought before the Royal Society. In this table all atomic weights have to be whole numbers, and argon and its companions have to form diatomic molecules; these and other things *have* to be what they have been demonstrated *not* to be, so far as the most careful, accurate and trusted work of a generation of chemists can be said to have afforded any demonstration at all.

One would expect some compensation for this; but in exchange for our most precious experimental data I can

find nothing more substantial than a number of integers which mutely stand and wait for elements not yet discovered, or not yet isolated in as pure a state as may be possible.

I suppose we must view this table, and in fact the whole article, in the light of Prof. Armstrong's dictum,

> "that imagination and even sentiment play an important part in chemistry, and that if too narrowly and rigidly interpreted, facts may become very misleading factors."

I do not know that this is true, but I feel convinced that the ruthless treatment which facts receive in this new table is not calculated to further exact science.

I must pass over the doctrine of residual affinity and the view of chemical combination as reversed electrolysis which figure so largely in the article. Their application to facts involves a most intricate discussion. These views have been before the chemical world for many years, and I do not think the measure of acceptance which they have gained warrants the prominence which Prof. Armstrong gives them in a general article.

Lastly, in dealing with the ionic theory Prof. Armstrong begins, it is only fair to say, by giving an impartial account of it, with illustrations of its application to chemical phenomena. He adds to this a reiteration of his own objections to the theory and an exposition of possible alternatives which he thinks preferable. This may be allowable, but I cannot pass over the serious charge which is made, that

> "the advocates of the dissociation hypothesis have declined even to consider the objections which may be raised to it from the chemist's side."

I am aware of the historic fact on which this statement is based, but I consider it most unfair to leave the reader of the Encyclopædia article under the impression that the ionic theory is entertained as a dogma by the large number of eminent chemists in whose hands it has been the means of effecting such remarkable advances of knowledge.

I do not wish, of course, to imply that in this article Prof. Armstrong has done otherwise than give an honest account of the state of chemistry as it appears to him, and I affect no claim to compete with him in dictating the true faith. But I do say that the whole article is so imbued with the peculiar opinions of the author as to be the polemic of an individual rather than a description of the state of chemistry as it appears to the vast majority of those who follow the craft. For this reason it does not appear to me to be well suited for an encyclopædia.

ARTHUR SMITHELLS.

SUBMARINES.

Les Bateaux Sous-Marins et les Submersibles. Par R. D'Equevilley, Ingénieur Civil des Constructions Navales, Ancien Ingénieur aux Forges et Chautiers de la Méditerranée. (Paris: Gauthier-Villars, 1901.)

IT is curious to note the difference in the general appreciation of the submarine in England and in France. Here until recently these engines of destruction do not appear to have been taken seriously by our professional guides, and, so far as the public know, but little has been done to prove their value, whereas in France, not only are there many already belonging to the Navy, but public appreciation of their utility is such that engineers will have to make themselves familiar with their history and their present lines of development. A handy little book such as this at three francs is likely, therefore, to find a ready sale.

The first chapter relates to the history of the subject under the heads of the different countries. It is interesting to us to note that the earliest submarine mentioned, *La Hollande*, was constructed on the Thames in 1620 and was worked in some way by oars, greatly to the delight of James I. The English have not done much in this line, nor have they been greatly encouraged by the authorities, for we are told that Johnson, early in the nineteenth century, navigated under the Thames in a submarine, which was confiscated by the Government on the pretext that he was going to deliver Napoleon. The builder of the submarine and of the motor-car seem to have been about equally stimulated.

It is surprising to see how, in almost every country but England, the problem has been attacked by many inventors, France apparently taking the lead.

The conclusion of the second chapter, that "habitability" is the most easy thing to attain, is not what would be expected, nor does it seem quite to agree with the accounts of the exhaustion of the men that have appeared at times in the newspapers.

The description of the view obtained from a submarine is interesting. At the depth of only a few metres it appears as if the boat is at the centre of a great circular hall without a roof, as refraction prevents skylight from penetrating beyond the critical angle. It is interesting to contrast this with the appearance of the earth seen from a balloon. Here the observer, as the effect of perspective, seems to be in the centre of a vast concave bowl. The colour of the water is described as favourable for lighting by the electric arc, as the course can be seen for 50 metres ahead.

Under the head of security, the author offers some rather chilly comfort, for he explains that as the submarine is of necessity of about the same density as the water, if you chance to run on a rock there is very little to prevent your glancing off, whereas with a surface-boat the weight at once prevents its rising in a similar way. It must, however, be remembered that if a liner merely scrapes laterally against quite an insignificant iceberg the plating is ripped off as long as the contact lasts. Of course, in consequence of the higher speed and greater dimensions, inertia is far more formidable in this case, but it is difficult to believe that even a submarine could do much rock scratching with impunity. Lest, however, anyone should become too confident, the author points out that one danger always exists—that of not being able to go up, up, up. For this reason the system always employed in French submarines has much to recommend it. These, even when they descend, retain a considerable buoyancy tending to make them rise, but they only actually descend by the action of horizontal rudders or aqua planes corresponding to the aëroplane of a flying machine. Such an arrangement will not permit of remaining below the surface voluntarily when at rest.

The chapter on the discharge of torpedoes is necessarily disappointing, as the author is unable to disclose information of a confidential nature.

The most interesting chapter is that which deals with the different stabilities on which the successful navigation depends. There can be no stability of buoyancy when totally immersed; the vessel either rises to the surface, or if it is ever so little heavier than the surrounding water it descends with ever-increasing velocity as the shell becomes compressed until the bottom is reached. When, however, the ship is moving longitudinally, the horizontal rudders determine the rise or fall. The author has no word of commendation for the method of rising or sinking by means of vertical screws.

After discussing shortly the interesting question of lateral stability when floating and when immersed, the author proceeds to the explanation of the effect of the position of the horizontal rudder on the good behaviour of the ship when diving. It seems that the old contest between rear and front steering wheels in tricycles has its counterpart here, and that the front steering, as in the other case, leads to more steady and certain results. The stability of direction depends upon there being plenty of length with fine lines aft. We are told that the submarine of the French Navy, after a run under water of several miles, can come to the surface again on exactly the same course as that which was followed at first.

A series of chapters on motors—steam, electric, petrol—and on tactics bring the author to his conclusion, which shows that he and the French Navy are in grim earnest, and that in his opinion so powerful and insidious a weapon will make naval warfare too terrible to be tolerated any longer. However confident the author may be, and whatever the truth may be, there is in this country much scepticism as to the power of the submarine, as will be gathered from an excellent article in the current number of *Whitaker*, p. 694. C. V. B.

THE DYNAMICAL FOUNDATIONS OF THERMODYNAMICS.

Elementary Principles in Statistical Mechanics. By J. Willard Gibbs, Ph.D., LL.D. Pp. xviii + 207. (New York: Charles Scribner's Sons; London: Arnold, 1902.) Price 10*s.* 6*d.* net.

WHERE a branch of science has been approached exclusively from the deductive side or exclusively from the experimental side, it is far easier to form a correct estimate of our state of knowledge in it than is the case where experimental and deductive methods have been continuously worked side by side. The study of rational dynamics has afforded excellent mental training for those who have made the greatest marks in the world as physicists, notwithstanding the fact that the conclusions arrived at in rational dynamics are in direct contradiction to ordinary experience. Thus it is impossible to verify experimentally that the times taken by *particles* to slide down *perfectly smooth* chords of a vertical circle are equal, and the phenomena of Nature are far too complicated to allow of an experimental test of the velocity with which a boy would have to throw a cricket ball *in vacuo* in order to give it a horizontal range of 200 yards. In the study of thermodynamics, on the other hand, where the experimental has preceded the deductive treatment, as has been the case ever since Joule discovered the so-called mechanical equivalent of heat, much confusion and failure to appreciate correctly our state of knowledge have necessarily resulted, and the only way of evolving order out of chaos is to formulate a theory on a purely deductive basis founded on certain hypotheses. The interest of the theory from a physical standpoint will then depend in the agreement or want of agreement between the conclusions of the theory and the results of observation.

In his study of the equilibrium of heterogeneous systems, Prof. Willard Gibbs, starting from the deductive side, gained a point of vantage which has proved of the greatest possible value to the experimental physical chemist. In his present work the same author is to a large extent following in the footsteps of Boltzmann, Watson and other writers, but at the same time he is imparting a great amount of his own originality, both in form and in treatment, to their work. It is impossible to read this volume without feeling that Prof. Gibbs has been to a great extent imbued with the same spirit which led Dr. Watson to produce the second edition of his excellent treatise on the "Kinetic Theory of Gases." This is a valuable feature, for it would be difficult to produce in a small compass a better introduction to the purely deductive study of the kinetic theory than has been given us by Dr. Watson. But Prof. Gibbs has gone further, and has not only discussed the subject at somewhat greater length, but by clothing the investigation in new language, under the title of "Statistical Dynamics," has presented it in a form in which it can be studied quite independently of any molecular hypothesis as a purely mathematical deduction from the fundamental principles of dynamics.

The study of statistical dynamics is based on the consideration, not of a single body or system, but of a very large number of such systems, and such a collection Prof. Gibbs calls an *ensemble;* moreover, in the course of the work it is found necessary to distinguish between *grands ensembles* and *petits ensembles*. The principle underlying the whole investigation is the well-known determinantal relation (corresponding to § 8 of Watson's book) connecting the initial and final values of the multiple differentials of the coordinates and momenta of an *ensemble*. The precise meaning of this relation has always been exceedingly difficult to grasp. It surely adds considerably to our clear understanding of the property to have it now enunciated as the "principle of conservation of extension in phase." A slightly modified form of enunciation gives the principles of conservation of density in phase, and of probability of phase. A further property is that extension in phase is an invariant in that it is independent of the choice of coordinates.

The most interesting distribution of the coordinates and momenta of an *ensemble* is that determined by a probability coefficient of the form $e^{-h\mathrm{E}}$ which is commonly known as the Boltzmann-Maxwell distribution. Prof. Gibbs calls this the *canonical* distribution, and the limiting case of $h=0$ where the coefficient of probability is unity is called the *micro-canonical* distribution. The

discussion of certain maximum and minimum properties leads to considerations of the changes which take place in an *ensemble* of system both when left to itself and when subjected to external influence, also of the results obtained by bringing two canonically distributed *ensembles* within influence of each other. The general conclusion is that there exist in statistical mechanics processes strictly analogous to many of those occurring in thermodynamics. Thus equations may be formulated closely resembling those which represent the irreversible heat-changes between two bodies of unequal temperature. When it comes to choosing a pair of conjugate variables to represent temperature and entropy, it is found that these are not uniquely determined, but that several systems are possible, a fact previously brought out, indeed, by von Helmholtz in his "Statics of Monocyclic Systems."

The last chapter deals with *ensembles* analogous to mixtures of different kinds of molecules, and these the author calls *grands ensembles*. They differ from the *petits ensembles* previously considered in the fact that they contain particles or systems of different kinds which may be present in different numbers.

Prof. Gibbs's work is not very easy to read, and it hardly seems appropriate to apply the title "elementary" to it; but the difficulties are no doubt inherent in the subject. It does much to elucidate the conditions under which a body composed of molecules obeying the equations of rational dynamics presents to beings of comparative dimensions similar to those of the human race attributes which may be summed up in the single word "temperature."

G. H. BRYAN.

AN ATTEMPT AT ORIGINALITY IN THE TEACHING OF ZOOLOGY.

A Course in Invertebrate Zoology. By Henry Sherring Pratt, Ph.D. Pp. xii + 210. (Boston, U.S.A., and London: Ginn and Co., the Athenæum Press, 1902.)

DR. PRATT'S book, defined on its title-page as a guide to the dissection and comparative study of invertebrate animals, is the latest of the many novelties which aim at effecting an improvement on the world-famous Huxleyean system, to which acknowledgment is made. The author sets out with the intention of enabling the student to study the larger groups as a whole, instead of detached types of different groups, as he claims is now generally done. In order to achieve this end, he deals in 174 pp. with no fewer than thirty-four representative animals, and the headlines of some of his chapters even bear the names of two alternative genera, for which a single description is made to suffice. Although this gives an average of little more than five pages for each animal, it must be admitted that, so far as they go, the descriptions and instructions, of necessity of a very elementary form, are lucid and correct.

Without going into further detail concerning the body of the book, it may be said that the essence of its novelty lies rather in the appendix and its associated classificatory scheme. This leads off with a copy of Claus's 1887 system, in which, as an all-conspicuous feature, the Sponges were classed as Cœlenterates, the Enteropneusta as Echinoderms. Then follows a short, but withal a useful, historical sketch of the growth of classificatory systems, from Cuvier to Hatschek, whose scheme of 1888 is given in tabular form, with a succeeding list of "short definitions" which are supposed to be *en suite*, and of which it is remarked that while not exhaustive they "are intended but simply to characterise the various groups in the fewest possible words." The first great subdivision is into subkingdoms (Protozoa and Metazoa), divisions follow, then types, classes, and orders. When, however, on comparison, one finds that while the table provides for five types (Spongiaria, Cnidaria, Trochozoa, Echinodermata, and Chordata), the three first-named are for the definitions numbered in order, and the two last-named are numbered five and six, one is led to seek for number four. The search is vain, since table and definitions do not agree. Most of the descriptions, moreover, in their would-be conciseness, are inadequate. And when with this it is said that, under type Trochozoa, defined as "Metagastrozoans whose common descent and relationship are shown by their possession in some form of a trochophore larva or of an embryonic form allied to it," there are included as subtypes Vermes, Articulata, and Mollusca, further comment becomes unnecessary, except to give it as our opinion that whatever the future of the zoological training of the young, it will not develop on these lines.

The above analysis might be extended with even humorous results; but whatever the good points the book may possess, failure appears to us certain in the attempt to do too much. The would-be new departure is foreign to the best traditions of the Huxleyean system. In the later development of this, the thorough mastery of type-structure has come to be regarded as an alphabet, by which the student learns to read, and the broadest possible survey of the structural limitations of the several groups of which the types are members, as a reading lesson to follow, under the special guidance of the teacher.

OUR BOOK SHELF.

Slide Rule Notes. By Lieut.-Colonel H. C. Dunlop, R.F.A., Professor of Artillery at the Ordnance College, and C. S. Jackson, M.A. (Barrister-at-Law), Instructor in Mathematics R.M. Academy, late Scholar Trinity College, Cambridge. Pp. 66. (London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd., 1901.)

THE slide rule is one of those things which can be less readily explained in writing than verbally. A few words explaining the principle so as to develop the slide rule sense is all that is required to put anyone of reasonable quickness in the way of becoming an adept. On the other hand, the full exposition of the logarithmic theory of the mode of setting for each class of operation, which is essential where the art is to be taught from a book, makes the thing seem so complicated and difficult to remember, that many who would find no difficulty in being taught by the first method might well give it up in despair at the very outset when taught only by the second method. However, it is not given to everyone to be able to find an adept with a power of exposition, and so the book becomes a necessity.

In the writer's opinion, the introductory chapter on the properties of logarithms does not furnish the most practical method, though of course it is eminently scientific, of showing the way to the use of the slide rule. But given that it is to be taught as school subjects are taught, *i.e.* so that the learner cannot see what the object is until he has arrived there, there is nothing but commendation for these notes, as they are called. Many as the books are on the slide rule, the writer of this notice has never seen one so complete and so logical. In addition to the regular uses which are always explained, though many who are familiar with the A, B, C and D lines fight shy of the trigonometrical lines, the solution of quadratic and cubic equations, exponentials and the plotting of curves are illustrated by many examples. Dr. Roget's log. log. line is shortly described, but no reference is made to Lanchester's radial cursor, which makes thermodynamical calculations with γ-wise exponents almost as direct as plain multiplications, and far more convenient than with the log. log. line.

One unfortunate misprint occurs near the beginning, where the construction of the rule is being explained, and the distance from 1 to 2 or log 2 is stated to be 3·03 instead of 3·01. C. V. B.

Injurious and Useful Insects: an Introduction to the Study of Economic Entomology. By L. C. Miall, F.R.S. Pp. viii+256. (London: George Bell and Sons, 1902.) Price 3*s.* 6*d.*

THIS little book is unfortunate in its title. One would expect to find all its pages given up to economic entomology; instead we find much valuable space taken up with long accounts of a carnivorous water beetle (*Dytiscus marginalis*), pp. 32 to 37; the tiger moth (*Arctia caja*), pp. 58 to 62; the harlequin fly (Chironomus), pp. 100 to 125. What such subjects have to do with economic entomology it is difficult to understand. At the same time, some interesting accounts of various economic species and groups are given, such, for instance, as the cockchafer, wireworm, turnip-flea, the gooseberry saw-fly, the hive bee, the silkworm, aphides and scale insects, &c. The accounts of the life-histories of these are all interestingly and accurately compiled, but when the practical part comes the work fails; compilation mainly from foreign sources, unless backed up by practical experience of such matters, is usually fatal.

For instance, no mention is made of trapping the adult click-beetles, the parents of the ravenous wireworm, yet it is the only way any good is done; nor is the practice of growing a crop of mustard on wirewormy land mentioned, and what is the use of advising the American remedy for the ground form of woolly aphis—tobacco-dust dug into the soil—in this country? The work is divided into four parts, dealing with the following subjects:—Part i., preliminary lessons, giving an excellent account of the structure of an insect; part ii., lessons on common insects, chiefly such as are either useful or injurious to man.

Part iii. deals with classification, and gives a concise outline of the different groups of insects; this is the most useful portion of the book. The names given to a good many insects in this part are, however, unfortunately not quite accurate; for instance, on p. 192 all the aphides, *rosae*, *humuli*, *mali*, &c., are put as belonging to the genus Aphis, which is not the case; nor is the name of the diamond-back moth *Plutella cruciferarum*, nor is that of the wheat midge *Cecidomyia tritici;* there may be an excuse for specific names being inaccurate, but surely not for generic ones.

Part iv. deals with the destruction and mitigation of insect pests; this is mainly compiled from American sources, the writer evidently being unacquainted with any work done in this country. Certainly here no one would dream of following the advice given on p. 246, "Paris green may be applied without danger at the strength of 1 lb. to 150 gallons of water." No mention is made of quassia wash or caustic alkali wash, so largely used in this country. The whole chapter is, in fact, but a poor account of the subject.

The work is illustrated with 103 figures, the majority good, but the reproductions of Bracy Clarke's bot-flies (Figs. 81 and 82) are scarcely recognisable; nor would anyone recognise the larva of the gooseberry saw-fly (Fig. 56), or the goat moth and its larva (Figs. 48 and 49).

To the pure entomologist the work will prove interesting and instructive reading, but it cannot be recommended to those who wish to study the economic side of the subject.

Chloroform: a Manual for Students and Practitioners. By Edward Lawrie, Lieut.-Colonel I.M.S., &c. Pp. 120. (London: J. and A. Churchill, 1901.) Price 5*s.* net.

THE book before us will be read with interest by those in whose memory the chloroform polemic is still green. It consists essentially of a physiological and clinical part. With regard to the former, Dr. Lawrie gives a history of the polemic between Drs. Gaskell and Shore and himself, extending from the first publication of the Cambridge physiologists upon this subject to the discussion at Toronto in 1894, in which, in the author's words, "the victory, which was decisive and permanent, rested with us." In addition to this historical sketch, the author gives certain experiments from the report of the Hyderabad Commission, some experiments made subsequently at Hyderabad, and some made by Prof. Rutherford upon the effect of stimulation of the vagus nerve during the inhalation of chloroform. These experiments are all illustrative of the action of chloroform upon the circulation, and are adduced by the author in support of the thesis that chloroform has no direct paralysing action upon the heart. The rest of the book is devoted mainly to the clinical aspect of the subject, the author entering fully into the technique of chloroform administration. Here he maintains strongly that the entire attention of the anæsthetist should be devoted to the respiration, and that no chloroform should be administered during struggling. The last chapter is devoted to the question of the statistics of chloroform and ether administrations. The author's statistics of chloroform show one death in 17,300 administrations; those of Mr. Roger Williams one death in 1236 chloroform and one in 4860 ether administrations.

Les Limites de la Biologie. Par J. Grasset. Pp. iv + 188. (Paris: Felix Alcan.) Price 2f. 50c.

PROF. GRASSET'S book is based upon a lecture he delivered at Marseilles in April of last year; we have here, however, not only the substance of that discourse, but numerous extracts from the writings of philosophers and men of science of many countries in support of the author's thesis. It is urged that biology is not the universal and unique science which some of its exponents claim it to be; and an attempt is made to describe its limitations. In separate chapters of his book, M. Grasset considers biology in its relation to the physicochemical sciences, to morality, psychology, æsthetics, sociology, mathematics, logic, metaphysics and theology. Whether the reader agrees with the conclusions or not, he will be interested in this exposition of the views of a medical man who believes there are parallel lines of progress along which human knowledge will continue to grow, and that these lines cannot from the nature of things intersect.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Heights of Sunset After-glows in June, 1902

THERE was a very fine example of red sunset after-glow visible here on the evening of the 26th ult., which presented with rather remarkable appropriateness to the date of its appearance, as immediately occurred to me while watching the impressive sight, a scene of transcending splendour of nature's own elaboration which could hardly have been much surpassed in grandeur by what England's great display of rare illuminations on that night would undoubtedly have been, if a check most sorely sad and grievous had not interposed a throb of deep sorrow on the nation, eliciting good proofs of its heartfelt sympathy and loyalty so universally and strongly as to prevent those sumptuous light displays from being used as auspiciously as they were hoped to be to celebrate the joyfully expected "Coronation-day" of 1902. The sun set at about 8h. 25m. with its orange-yellow disc unhazed, and only shorn of rays by a few faint cirrus cloud-streaks close to the horizon, the sky being elsewhere apparently quite free from clouds. At about 8h. 40m. a long low belt of sky extending 70° or 80° along the northwest horizon had grown orange-yellow, streaked with a few faint lines of red and gradually diluted upwards at a height of 15° or 20° into pale shades of light yellow. A ruddiness of the sky in the east had at the same time risen nearly to the zenith, and through its natural blue tint there the sky passed gradually to white about half-way from the zenith to the west horizon, while under this white tract (about 30° in width) lay the bright belt of orange light with its shades of yellow gradually deepening downwards. But at about 8h. 45–50m. the pure white interval between the ordinary blue and the yellow-tinted regions was gradually invaded, and at last quite occupied, by the advancing ruddy colour from the east; and until about 8h. 55m. a space from 30° of altitude in north-west to near and somewhat beyond the zenith, and for 40° or 50° to either side of a vertical line through the place of sunset, presented a broad expanse of rich rose-coloured, lake-red light pervading all the sky's north-western quarter with a fine wide blaze, against the purple glare of which tall trees and houses all looked sharply silhouetted, and for a short space of about ten minutes that the rose-red colour lasted, all objects of the landscape facing towards the west looked conspicuously crimsoned. The ruby-tinted glow sank rather rapidly in height, and by 9 p.m. it had subsided into the summit of a lower and far brighter pinkish-orange bank of light about 30° high, the lower layers of which formed a belt 12° or 15° in height stretching for about 90° along the west-to-north horizon in a blaze of yellow amber or of ochre-yellow colour. No radiating streamers or shadow-beams crossed either the previous purple glow or this orange-reddish dome-like bank of light; but the latter light-field's splendid flood of unflecked, evenly-spread colour sank very gradually, preserving its length, to 12° or 15° in altitude by 9h. 15m., growing less ruddy, and assuming pretty uniformly then throughout the horizon layer's yellow-ochre colour. As its brightness had then very sensibly diminished, no further watch was kept on its later changes of appearance.

The time of occurrence of the true rose-tinted glow, when the white space's illumination was replaced, and then swept down into the sunset-glow, by a westward coursing wave apparently, of rose-tinted light, was about 8h. 50–55m. when at its brightest, or about 25–30m. after sunset, when the sun was therefore about 3° below the horizon here, and when the earth's shadow-surface cast by the sun through the air above this point of view was about five miles from the earth's surface. The finely divided matter which by a red-bordered coronal or "Bishop's ring" effect[1] of diffraction, probably, on an exceedingly wide-circle scale, bent downwards into view from nearly overhead the sun's parting rays in the westward coursing way which seems to be quite general in these dust-caused colour-glows, and with red colour made rosy, probably, by mixture with the sky's ordinary blue, must thus, it appears, have been at no very considerably greater height in the atmosphere than about five miles; or at about the ordinary floating level of cirrocumulus and cirrostratus clouds.

A few less radiant after-glows of rosy tinge appeared here when the sky was clear, on June 17 and 21; but no perceptible traces of rose colour occurred in the pallid sunsets of June 23 and 25, although the sun went down on the latter date behind a faint low bank of cirrus cloud, surrounded by a splendid orange-yellow "glory" about 10° wide, very suggestive of "Bishop's ring," as it was shaded off by redder colour at its borders. As the last visible spark of the sun's bright orange body disappeared in a little cleft, apparently (for it lingered there for a second or two), of a tree-clad hill horizon four or five miles distant, it was white (and the same was noted on the 26th), and showed no greenish coloration.[1] Under the north-western edge of a thick cloud-veil which overspread the sky on Sunday evening, June 22, a belt of sky about 40° long and about 10°–15° high was brilliantly ablaze, from 9h. to 9h. 15m., with light of orange-yellow colour slightly streaked with red, and presented, among fragments of dark cloud dispersed across it, an almost terrifying resemblance to reflection in the sky of an immense distant conflagration. On June 24 a ruddy yellow glare widely pervaded the clear sky to a high altitude in N.W. from 8h. to 8h. 30m., but I was not fortunate enough among obstructions of its view in London to obtain any observations of its changes. On two other evenings, however, Friday and Saturday, June 27 and 28, sufficiently clear views of the rose-tint were seen, the times of apparition of which were recorded, to afford additional determinations of the real height of its appearance; and the following are some details of the pink glow's aspect on the three or four dates besides June 26 when its successive changes here were pretty clearly recognised and were approximately noted.

On June 17, the first clear evening after a cold, rainy fortnight, a pale cochineal tint, in the north-west, of the beautifully transparent sky was first quite plainly noticed, at 9h. 10–15m., of some width and at an altitude of about 10°–30°; although a similar, but rather weaker, pink glow had already before been seen with rather less distinctness on the last two nights of May; and on this evening it faded out by 9h. 15m., sinking down into a brick-red light-glare 5°–10° high, which by about 9h. 20–25m. grew dull orange-yellow and then faded. The first commencement of the glow was not seen, but as it was probably near its

[1] The ring was thus described by Mr. S. E. Bishop, at Honolulu, in NATURE (vol. xxix. p. 260, 1884, January 17):—As "a very peculiar corona or halo extending from 20° to 30° from the sun, which has been visible every day with us, and all day, of whitish haze with *pinkish* tint shading off into *lilac* or purple against the blue . . . It is hardly a conspicuous object." In the growing dusk, however, of an hour after sunset. the ring of pinkish white and purple, probably produced by admixture of the sky's ordinary blue with the yellow, orange and red parts of a pure corona, however weakly visible in full daylight, might yet in twilight look bright enough to be easily distinguishable; and the gradual shrinking inwards of this distinct red bordered ring from nearly overhead towards the west as the remaining upper levels of the atmosphere still lighted by the sun's rays grow every moment loftier, must pretty surely indicate that the first red light to fade away, or that beginning nearly overhead and furthest from the sun, belongs at once to both the lowest and the finest-grained dust-layers of the corona-forming haze; a conclusion nowise inconsistent with a usually experienced property of mists that they most commonly become coarser-grained in retreating inwards from their borders.

[1] The earliest mention that I have seen of the "green-flash" at sunset, as having been sometimes observed on the sea horizon from Bude, in Cornwall, by the Rev. G. H. Hopkins (NATURE, vol. xxix. p. 7, 1883, November 1), concludes with a remark that the effect was not produced when the sun set behind a distant cloud, and that it might very probably be also seen at sunrise. This last conjecture was immediately confirmed (*ibid.*, p. 76) by Prof. W. Swan, who wrote from Edinburgh that when watching for sunrise on the Rigi, on the very clear morning of September 13, 1865, he saw the sun appear with a dazzling blaze, for the first instant, of superb emerald green colour, from behind the sharp outline of a distant mountain. It may be interesting to add here, with respect to the other condition noticed by Mr. Hopkins, of the green flash not being apparently produced by the sun's descent behind a cloud, that having been myself, with three others (two of us using binocular field-glasses), well placed on April 22 last for trying to observe the totally eclipsed moon in the east and the setting sun in the west above the horizon together, the sun at least, after a cloudy and rather stormy day, set in an opening of clear sky, behind a low bank about 2° or 3° high, of sharply edged, opaque and solid-looking cumulus which, judging from the ten miles distant ridge of hills at Cookham, very far behind which the cloud-bank seemed to lie, could hardly have been less than 20 or 30 miles from our position. Passing the word to "look out for colour," when the sun's upper limb was nearly disappearing, we all exclaimed "green!" together, as the last and most northerly light-speck of three bright beads into which the sun's upper limb broke up at last lingered for not much more than half a second after the other two, both of which looked rather whiter than the last, when fading, and then vanished. Of the last spark's distinctly green colour there could be no doubt, and it inclined rather to a yellowish than to a blue shade of green. A thin thread of yellow light, like an extremely slender, short, crooked horizontal lightning flash, fringed the dark cloud's upper edge for a few minutes, behind which, at about 7h. 15m., the sun had descended; and beyond that the clear sky was nearly grey, and until about 7h. 30m., like the sun's disc itself, very free from yellow and orange sunset colours.

brightest at 9h. 10m., 45 or 50m. after sunset, when the sun would be $5\frac{3}{4}°$ below the horizon, its real height above the earth, making proper allowance for its low altitude of 20° and for the sunlight's refraction, was about 13 miles; while its low angular distance from the sun probably denoted a not very excessive fineness of the sunlit haze material.

On June 21, at 8h. 53-56m., or about 30m. after sunset, a wide expanse of pink glow was seen in the upper parts of three broad streamers radiating not far from vertically upwards, to altitudes of about 30°, from the sun's place. The streamers sank in altitude to about 20° by 9h., and subsided gradually by about 9h. 5m. into the summit of a ruddy yellow light belt extending about 90° along the horizon in the sunset quarter to altitudes of 8°-15°. This bright tract grew duller yellow and orange at its base and borders, until about 9h. 20-25m., when it had nearly faded out. At 30-35m. after sunset, when the streamers' crests at an altitude of 20-30° glowed visibly with rosy light, the sun was $3\frac{1}{2}°$ or 4° below the horizon here, and the height of the red coronal glow produced there by the sun's parting rays must have been about $6\frac{1}{2}$-$8\frac{1}{2}$ miles above the earth.

For nearly half an hour after sunset on June 27, the clear north-western sky showed only weak dull shades of yellow, but a long low belt of this at the horizon attained some intensity at 8h. 45-50m., when a short arched band of level cloud streaks grew pink at first and then bright crimson on their lower edges, and from 8h. 50m. to 9h. presented there a splendid interlacing network of red stripes about 35° long and 4° high. At the latter hour pink streamers radiating from the hidden sun as centre and springing chiefly from the northern upper portion of the yellow light belt began to be visible, two immensely long and very narrow straight ones leaving it at about N.N.W., altitude 8°, with slopes of 15°-20° from horizontal, and reaching out, 3° or 4° apart, through 53° or 60° to somewhat beyond N.N.E., ending at altitudes there of 15°-20°. The upper and stronger one was pink towards its end, but where they joined the light belt most brightly, and passed through north at altitudes of about 10°-12°, they partook of the light belt's reddish yellow colour; above them some much shorter and weaker pinkish streamers soon appeared, and at about 9h. 15m. two rather tall wide patches of faint rosy pink were formed at an altitude of 25° or 30° above the sunset place, by two nearly vertical wide streamers, and remained visible with pink colour for some minutes. While travelling here by train from London during its appearance, I could not note the early stages of this glow's commencement, and my whole view of it was very partial; but from the pink tint's visibility from 9h. to 9h. 15m. at an altitude of about 20°-30°, at about 40 or 50m. after sunset here, when the sun was $4\frac{3}{4}°$-6° below the horizon, the heights of the pink crests of the radiating streamers would seem to have been, not very accurately, about $12\frac{1}{2}$-20 miles above the earth.

A most complete view, however, of the successive features of the purple glow was obtained here on the evening of Saturday, June 28, when the concluded height of its appearance so surprised me by its unexpected lowness as to lead me to examine also the foregoing observations with a view to a general comparison together of the glow's real heights that would be found to be derived from my notes of it on different evenings. The sky was then streaked with cirrostratus cloud-seams ruling it with fan-like convergence towards about the sunset quarter; but except in that direction those fleecy stripes dispersed by about 8h. 40m., and the nearly clear north-western sky half-way to the zenith was pale yellow, passing above about that altitude into greyish white, and beyond the zenith into blue. At 8h. 50-53m., the yellow sky-zone's colour having deepened and the grey-white tract above having descended to about altitude 40°-45°, the latter space grew rapidly rose-pink and round its centre a nearly circular field about 40° in diameter displayed pale pink oleander-flower or almond-blossom colour. Ending upwards, under this, in light straw-yellow, lay the wide-arched summit of a pretty strong horizon glow about 20° high over the sun's place and about 30° long in span to either side of it, of ochre-tinted yellow. The rose-pink coloured space sank gradually, or died out from above, between 8h. 55m. and 9h., replaced from behind by greyish and blue sky and invading the pale straw-yellow summit of the arched horizon-glow, which together with that whole glow, by about 9h. 5m., grew orange-red throughout. This litharge-red, and a little while later fan-tail-looking, glow contracted slowly downwards until 9h. 15m., when as it was growing dim and inconspicuous I ceased to watch it. But in the last 10m. its upper border had in its usual way, when beginning to grow red, broken up into bright radial streamers crossing what remained visible of the cirrus streaks at such appreciable angles as to show them to be true solar light-beams quite unconnected with the wind-imparted radiation of those cloud-streaks from a near neighbouring but different focal centre. Where a long and well-defined straight radial streamer shooting up obliquely southwards crossed some of those faint cloud-streaks' strongest ripples, their gauzy cloud materials certainly did not add to its brightness; but at the same time, they diminished the streamer's light so much less than that of the grey sky immediately adjoining it, that they could hardly be said to have very distinctly screened and darkened it.

As the sun's parting illumination of the sky with rosy colour, from altitude about 50°-60°, downwards, in this sunset, occurred (at about 8h. 55m.) not much more than 30m. after sunset here, when the sun was $3\frac{1}{2}°$ below the horizon, it would follow that this red illumination by direct sunbeams, of microscopically fine haze matter took place at about $7\frac{1}{2}$ miles above the earth, or apparently not far from about the probable real heights of the simultaneously noticed cirrostratus cloud-streaks.

The chief features of these recent after-glows having been just the same as those which were generally noticed during the gradual subsidence of the volcanic after-glow appearances in 1883-4, since it was then pointed out by some investigators of their real heights that some white cloud-wisps looking phosphorescently bright long after dark, and even sometimes, near the horizon in the north, throughout the night, must have been floating far above the ordinary height limits of rain and snow clouds produced by aqueous vapour, I was led by the comparative lowness of these few new height conclusions to consult the original accounts given in NATURE by many good observers of the sky-glows in 1883-4, to recall more exactly than I could certainly remember what real heights had then been actually assigned to them. In such letters as Mr. F. A. R. Russell's, at Haslemere (NATURE, vol. xxix. p. 55), describing the evening sky-glow on November 9, 1883, as having twice pervaded the sky with rosy red, beginning from overhead, first at 5h. and again at 5h. 40m. (or at 42m. and at 1h. 22m. after sunset at 4h. 18m.), and as having gradually settled down into the greenish-yellow glare at the horizon in about 20-25m., it is quite evident that much loftier heights of the pink glow were then indicated than those which have just now again been essayed to be determined. The sun, at these two glows' commencements, would be about $5\frac{3}{4}°$ and $11\frac{1}{2}°$ below the Haslemere horizon, and the corresponding vertical heights over Haslemere of its earth-grazing beams would, allowing about $\frac{1}{2}°$ for their downward deflection by refraction, be about 17 and 75 miles above the earth.

In letters from Mr. J. E. Clark at York and from Mr. J. Ll. Bozward at Worcester (*ibid.*, pp. 130-131), the sky-glows from November 27 to December 4, 1883, were similarly described, in general, as usually attaining their strongest and brightest redness about one hour after the time of sunset, with durations afterwards of the fiery-looking dying-out phase of the glow for nearly an hour longer. Although these observations were not made with certain enough discrimination of the exact times of the rose-red tints' commencements to afford very definite determinations of their real heights, yet in their records of about one hour after sunset, at which the whole height and width of the sky assumed an especially imposing kind of red magnificence, they were for the most part pretty perfectly accordant. At an hour after sunset on December 1, the sun would have sunk about 7° below the horizons of York and Worcester, and the height above the earth of fine dust-haze beginning to shine then overhead with red illumination would be about 25 miles. But determinations of the pink glow's real height by the method which has here been used, and of the warrantableness of which the roseate displays' frequent collection into tufted heads of real sheaf-like sunbeam radiations is itself a sufficient proof to afford us full assurance, were in fact actually obtained on November 25-26 and 29, 1883, and were communicated in letters (*ibid.*, p. 103 and p. 130) by Annie Ley, at Ashby Parva, Leicestershire, and by R. von Helmholtz, in Berlin, who concluded it to have been at upwards of 13 and at about 40 (? more nearly 30) miles high respectively. The intervals after sunset when the wide red glow began in these two latter cases were about 50-60m. and a little more than one hour, resembling the generality of other observers' records, in those

most gorgeously coloured, long-enduring sunsets, of the times of the conspicuous red glows' commencements; but this average interval appreciably surpassed the shorter space of 25–50m. (as did also the fading-out duration of nearly an hour exceed that of only 20-25m.) observed in last month's displays; and the computed heights accordingly of the glow-producing matter ranged considerably lower (from 5 or 8 to 13 or 20 miles) in these latter than in the memorable sunset glows which followed the great eruption in Java on August 27, 1883, when heights appear to have been found of 13 or 17 to 25 or 30, or even possibly of 40 or 70 miles, for the strata of the atmosphere contaminated with volcanic dust.

The relative height results and the comparative intensities of the present and of the former glow displays seem, however, to have been in quite naturally comprehensible agreement with the lower height of projection, and with the generally lesser magnitude of the recent fearfully destructive outburst on the islands of Martinique and St. Vincent, when compared with the terrifically violent and immense volcanic explosion of Krakatoa in August, 1883, which is generally admitted to have had no previous parallel, in respect of scale and violence of mountain-mass ejection, in the history of such terrestrial convulsions. It will be interesting to notice on future nights if more examples of rose-red coloration should occur, when the times of the white and yellow sky-tracts becoming pink and ruddy should be noted, as the past month's rosy and fire-tinted sunsets were perhaps not quite sufficiently conspicuous to establish their certain connection with the terrible volcanic catastrophe of May 7-8 last in the West Indies. But considering the low temperature and continued cold soaking rainfall during all the early part of last month, until Sunday, June 22, it seems far from easy to conceive that the strikingly fine sunset display of Thursday, June 26, and the conspicuously rosy colorations of the sunset sky on June 27 and 28 can by any possibility have been merely sunset glares produced by ordinary floating dust raised locally from parched or arid tracts of land by the heat and fresh east wind of those few days of the first short interval of summer warmth and sunshine in last month, on which they were observed.

Observatory House, Slough, July 10. A. S. HERSCHEL.

P.S.—July 16.—A very fine display of orange-reddish streamers diverging in an open fan of six or seven stately light-beams from a similarly coloured horizon glow, 6° or 8° high at their common base where the sun had set (at about 8h. 15m.), was seen here on Monday evening, July 7. From 8h. 50–55m., when these fiery-looking beams began to appear, up to altitudes of about 35°, across a rosy tract of sky which had sunk to the elevation of their growing crests from a higher region of pink colour first distinctly well perceived at 8h. 42–44m., their radiant light-sheaves shortened gradually without change of place or brightness; and they lasted thus quite 20m., retreating slowly into the decreasing glow at the horizon until that glow itself, at last, grew quite low and dull at 9h. 15m. The pink glow's lower border, when the first bands of streamers crossed it, was not more than 10° or 12° from the horizon, and the glow's red hue soon permeated all the yellow belt of sky which lay below it, while the streamers, at their heads, grew orange-red in place of pink, and thus from 8h. 50–55m. onwards, the whole display, until it subsided, was of one bright pinkish-orange tint in all its features. The new moon's very slender crescent, at 8h. 55m., lay less than 1° from the horizon, under the end part of the most southern streamer, looking pure yellow, and showed by its clear visibility how free from mist and smoky haze the sky was on that evening quite close to the horizon.

From the pink glow's first appearance at 8h. 43m. with an altitude of about 35°, at about 28m. after sunset, the resulting real height of the layer of dusty air which was thus lit up by the sun's departing rays, could not much exceed 5 miles above the earth's surface. On other dates in July before and since that notable appearance, the observed occurrences of a pink tinge in the sunset sky were scarcely noticeable, and the estimated time of its first appearance was only once thought to be pretty certainly trustworthy, on Sunday, July 13 A rosy tinge then first presented itself pretty brightly at 8h. 41m., about 33m. after sunset, at about altitude 40°, sinking down along the heads of some nearly vertical wide streamers, in three or four minutes to altitude 15°–20°, where it soon died away. The height of the mauve-coloured haze-stratum in the atmosphere which this observation pretty nearly indicated would seem to have been about 7 or 8 miles.

In addition to the above short notes of some particular accounts contained in NATURE of the bright sky-glows of November and December, 1883, it was observed, I find also, by Mr. E. Douglas Archibald, at Rusthall, near Tunbridge Wells (NATURE, vol. xxix. p. 176), that after sunset (at about 3h. 51m.) on December 6, a bright silky-looking white space in the clear sunset sky changed to pink at 4h. 25m. (34m. after) and to red at 4h. 45m. (54m. after sunset), which would imply heights of the pink and red glows of about 8 and 21 miles above the earth. But from the appearance of the glow on December 7 and of its reflection on low clouds, Mr. E. D. Archibald remarked that the red light's long continuance after the pink glow's departure was mainly attributable to cloud or haze reflections of true red coronal glares about the sun; and the conspicuous tinging of the white space with pink or rosy iridescence he concluded, from the interval between the concluding glow of ordinary cirrus and the commencing glow of the loftier dust stratum, corresponded more nearly with a height of from 10 to 13 miles, than with the great height of 40 miles assigned to the glow (probably from long-lasting reflection of red glows in the west on low-lying clouds, or perhaps even on the high dust stratum itself) by Prof. von Helmholtz.

Distribution of Pithophora.

IN your Notes of July 17 you state that Mr. Kumagusu Minakata wishes to know if any species of the genus Pithophora besides *P. Kewensis* has been reported from any part of the Old World except Japan since 1877.

P. radians, West and G. S. West, was described from Loanda, on the west coast of Africa, in *Journ. Bot.* (January, 1897, p. 36), and has more recently been found in Ceylon (cf. *Trans.* Linn. Soc., bot. ser. 2, vol. v., 1902, p. 132). *P. Reineckii*, Schmidle, was described from Samoa in Engler's *Bot. Jahrb.* (xviii., 1896). Schmidle has also described at least one other species from the Old World, but I have not the reference to hand. It will be found within the last five years either in Engler's *Bot. Jahrb.* or in "Hedwigia." G. S. WEST.

Royal Agricultural College, Cirencester, July 18.

Saturn Visible through the Cassini Division.

IN NATURE of May 22 you were good enough to publish my prediction that, on July 17, the Cassini division of Saturn's ring would be invisible where it crossed the planet.

On July 15, Mr. Townshend, president of the Leeds Astronomical Society, reports that he saw the division throughout the ring and crossing the globe, but that on the 17th the portion crossing the globe was invisible. Mr. Townshend observed with a 10-inch reflector, and is a very competent observer.

On July 17 I was observing with a 9-inch refractor, and the Cassini division, clearly seen in the ansæ of the ring, was quite invisible in that part of the ring which crossed the globe.

I shall be very glad to receive notes of other observations of Saturn made on July 17, and shortly before and after that date.

Invermay, Leeds, July 21. C. T. WHITMELL.

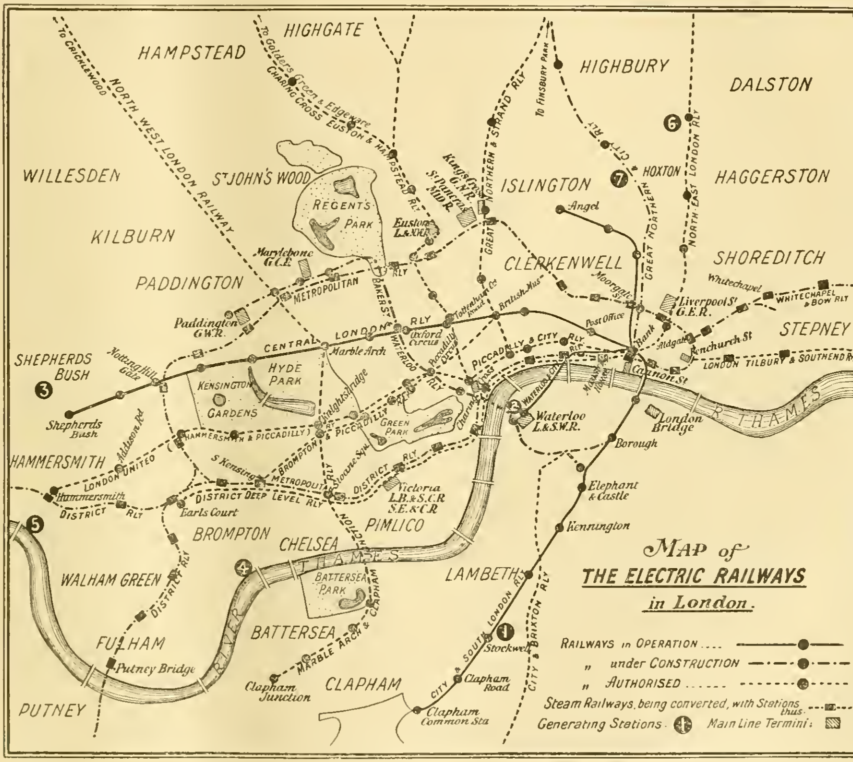
THE ELECTRIFICATION OF LONDON.

THE various electric railway Bills which have already passed through the House of Lords came up for second reading in the House of Commons last week. In spite of some attempts to reject several of these Bills they all successfully passed the second reading and have been referred to two Select Committees of the House of Commons. These Committees, each of which will deal with about half-a-dozen Bills, are to hold their first meetings at once, the one under the chairmanship of Sir L. M'Iver, the chairman of the other being Mr. Seale-Hayne.

The Bills have already been thoroughly investigated by the Select Committees of the House of Lords presided over by Lord Windsor and Lord Ribblesdale during April and May. These two Committees had much the more arduous task, as they had to deal with a larger number of Bills, several of which they rejected. It is possible, as a result of their work, to form some idea of

the probable effect of the proposed new railways in relieving the congested London traffic. It will be understood that it is assumed in the following article that the Bills which have passed the House of Lords will also pass through the Commons without any modifications of the first importance. In all, no less than twenty-four different Bills have come before Parliament this session relating to electric railways in London; of these eighteen were for new railways or extensions of authorised routes, one was for power to run an existing steam railway electrically, and the remaining five for extension of time for construction. The extension of time was in all cases granted, but it seems that the number of instances in which it was applied for had a notable effect on the decisions of the Committees with regard to other schemes. For it was the difficulty in raising the necessary capital which made application for extension of time necessary, and, as a result, where new railways were promoted the Committees required evidence that the promotion was financially well backed before sanctioning the lines. Of the eighteen Bills for new railways, many were directly in competition for the same route, so that it was inevitable that some should be rejected. Thus there were three different companies promoting Bills for a railway connecting Hammersmith with the city, one of these being the Central London Railway, which proposed to run the new line as a "circle" in conjunction with their existing route. This Bill was, however, rejected, the successful competitor being the London United Railways, which, working with the London United Tramways and the Piccadilly and City and North-East London Railways, will provide a through route from the extreme west to the north-east of London.

From the map which we publish in illustration of this article, the references to different railways will be easily understood. For the data for this map we are largely indebted to the excellent maps published from time to time in the *Electrician*. It shows only those lines the construction of which has been authorised (or which are in operation), and a different system of drawing has been adopted to indicate which railways are working, which under construction and which merely authorised. The engineering details, so far as they are yet decided, show a remarkable uniformity, resulting partly from the decisions of the Board of Trade, the Vibration Committee, &c., which have recently been given in connection with different difficulties arising in the construction and working of "tube" railways. Most of the new railways will be "tubes." The Hampstead-Edgware line, which is to be about 6 miles long, is to run in the open; it forms a continuation of the Charing Cross, Euston and Hampstead Railway shown on the map; so also will a few miles of



the northern end of the North-East London Railway which runs past Tottenham to Palmer's Green. Of course, also the Metropolitan and District Railways and the London, Tilbury and Southend Railway (which is authorised to convert to electric traction) will not run in tubes. In some of the railways the proposed diameter of the tube is 11 feet 6 inches, and in the others two feet larger than this, Mr. Yerkes favouring the smaller diameter for the railways under his control. The larger diameter allows of the construction of two platforms, one on either side of the train, for the use of passengers in case of an accident. These, with the electric lighting of the tunnel which it is proposed to carry out, will afford an easy means of getting to the nearest station should a train be stopped in the tube. With the smaller tubes it will not be possible to have these platforms, and passengers will have to use the permanent way as a means of escape. The smaller tunnels will also involve slightly raising the floor level of the motor carriages to allow room for the motor equipment, which will involve possibly slight inconvenience to passengers. Against these disadvantages must be set the diminished cost of construction. It is also claimed by Mr. Yerkes that the side platforms are really more dangerous than a platform along the permanent way, and would, moreover, be destroyed in case of a derailment.

The electrical details of all the schemes are very similar. Current will be generated as high-pressure alternating current, and transformed to continuous current at 500 volts for working the trains. The multiple-unit system has been adopted—that is to say, the trains will consist of two or three motor cars with three or four trailers, and will not be entirely of trailer cars drawn by a single locomotive. It is also noteworthy that both the conductors are to be insulated, the rails not being used as a return; in the case of the tubes of larger diameter, both conductors will be underneath and protected by one of the side platforms, whereas with the smaller tubes, one conductor, the positive, will be at the side of the track and adequately shielded and the return negative conductor will be between the rails.

The District Railway, including the deep-level line from Earl's Court to the Mansion House, the Brompton and Piccadilly, the Great Northern and Strand, and the Charing Cross, Euston and Hampstead Railways, all of which are under the control of Mr. Yerkes, are to be supplied with power from a generating station by the riverside at Chelsea (4). The generating pressure is to be 11,000 volts and the output 50,000 kw., the station being the largest for traction purposes in the world. The railways under Mr. Morgan's control are the Piccadilly and City, and the North-East London. These, with the two railways belonging to the London United Railways, viz. the Hammersmith and Piccadilly and the Marble Arch and Clapham Junction, in the former of which Mr. Morgan owns a half share, will be supplied with power from two generating stations, one in Fulham (5) having a capacity of 12,000 kw., and the other in the Kingsland Road (6) having a capacity also of 12,000 kw.; it is proposed to use three-phase transmission at 10,000 volts.

It will be seen from the map that although, on the whole, London will be very well supplied with rapid transit facilities when all the new railways are working, there are still some districts inadequately catered for. It must, however, be remembered that in many of these districts there are good tramways either running, or to be run, electrically. Thus, in the south-east corner of the map, the network of tramways is fairly comprehensive. In the north-west the Middlesex county light railways will help to bring traffic to the city. A tube railway for the north-east, connecting Waltham Abbey and Walthamstow with the city, was withdrawn owing to certain alterations in the city end of the route, but it is understood that a similar line will be promoted next session. Indeed, one cannot help feeling that there are for the present a sufficient number of railways in hand, especially when it is considered how many are being financed by the same people; it will be time enough when these are either running or well advanced in construction to promote other Bills for the more complete electrification of London.

The question of fares and through booking is likely to become of importance when all the railways are at work. At present opinion seems divided between the system of the Central London Railway and the more usual booking system. It would certainly seem that when the whole network is complete a through booking arrangement would be a great convenience to the travelling public. At present, whilst the railways are few and the number of cross connections still fewer, the matter is not one of much importance; but once it becomes possible to travel from almost any part of London to any other by electric railway, the journey necessitating possibly two or three changes of line by the way, the question is put on another level. This is, however, a consideration which may well be left for time and circumstances to settle.

We may conclude by a brief summary of the route and principal points of interest of the different lines.

(1) *City and South London Railway*.—This, the first electric railway in London, was opened in 1890. It has since been extended, and now runs from Clapham Common through the City to Islington. The original electrical equipment of the power station was replaced in 1900; the line is remarkable, as it is run on a three-wire system. The power station is at Stockwell (1), and has a capacity of 3000 kw. The train voltage is 500, and the rails are used as return conductors. Length of line 6¼ miles, and scheduled speed 15 miles an hour. The trains are drawn by locomotives.

(2) *Waterloo and City Railway*.—This railway was opened in 1898 to connect the L. and S.W.R. with the City. It has no stations beyond those at Waterloo and the Bank. Length of line 3 miles, speed 18 miles an hour. Multiple unit system used, 500 volts pressure, and rails as return conductors. Generating station at Waterloo (2), capacity 1300 kw.

(3) *Central London Railway*.—The railway was opened in 1900, and runs from Shepherd's Bush to the Bank. The western end is fed by the London United Tramways coming from Hounslow and Southall. The length of line is 6 miles and the speed 14½ miles an hour. Locomotives were originally used, but experiments with the multiple unit system have recently been tried on account of the vibration troubles, and the Company has just closed a contract with the British Thomson Houston Co. for 64 motor-car and 160 trailer-car equipments. The rails are used as return conductors. Power is generated at Shepherd's Bush (3) at 5000 volts; capacity of station 5100 kw.

(4) *Metropolitan and District Railways*.—The lines to be electrically equipped include the Inner Circle and the Hammersmith and Putney branches. They afford a means of approach to the City from the south-west, and also communication through various districts by means of the "Circle." The electrification will be completed in eighteen months or two years.

(5) *District Deep Level*.—This is to provide an express route from Earl's Court to the Mansion House running under the existing line. The line is authorised, but construction work is not yet begun.

(6) *Whitechapel and Bow Railway*.—This branch of the District Railways will be electrified with the rest; it affords connection with the London, Tilbury and Southend Railway at Bow.

(7) *Brompton and Piccadilly Railway*.—The line will run from South Kensington Station (District Railway) *viâ* Knightsbridge to Piccadilly Circus; the construction

work has just started. An extension to Holborn has been granted, where (besides connecting with the Central London Railway) it will form a junction with the

(8) *Great Northern and Strand Railway.*—This will run from Finsbury Park (G.N.R.) past King's Cross and Holborn to the Strand.

(9) *Charing Cross, Euston and Hampstead Railway.*—Starting at the Charing Cross end, the line runs to Tottenham Court Road, where it gives a cross connection with the Central London, thence *viâ* Euston to Hampstead (Golder's Green) and Highgate. At the Golder's Green end there is to be a junction with the

(10) *Hampstead and Edgware Railway.*—This is to run in the open to Edgware. The line, which is outside the limits of the map, is to be controlled by the Charing Cross, Euston and Hampstead Railway.

(11) *Baker Street and Waterloo Railway.*—This railway was authorised in 1893. Construction work is now considerably advanced. The line with the extensions granted runs from Paddington (G.W.R.) *viâ* Marylebone (G.C.R.), Baker Street, Oxford Circus, Piccadilly Circus, Charing Cross and Waterloo to the Elephant and Castle, where it connects with the City and South London Railway.

Mr. Yerkes holds a large interest in all the above railways (4–11). Power will be supplied to all (except possibly the two last) from the generating station in Lots Road, Chelsea (4), particulars of which have already been given. The Metropolitan Railway has, however, a separate power station at Neasden.

(12) *London United Railways (Hammersmith and Piccadilly).*—This line, which is promoted by the London United Tramways and half owned by Mr. Morgan, will run under Hammersmith Road, Kensington High Street and Piccadilly to the Circus. At the Hammersmith end it is fed by the tramways. At the Piccadilly end it forms an end-on junction with the

(13) *Piccadilly and City Railway.*—This line is to run from Piccadilly Circus to Charing Cross, and thence under the Strand and Fleet Street to the Bank. At the Bank there is an end-on junction with the

(14) *North-East London Railway.*—This railway runs from the Bank through Highbury and Tottenham to Palmer's Green (near Southgate). The last few miles are to run in the open. This, with the two above lines and the London United Tramways, will give a through route from the extreme west to the north-east of London. Through booking is to be adopted, the proposed fares being extremely small. The group is known as the "Morgan" group, and will be supplied with power from the stations at Fulham (5) and Kingsland (6).

(15) *London United Railways (Marble Arch and Clapham Junction).*—This line gives a south and north connection running from Clapham Junction *viâ* Sloane Street under Hyde Park to Marble Arch. It is promoted by the London United Tramways Company, and will obtain power from the same station as their other railway. At Marble Arch there is connection with the Central London Railway and an end-on junction with the

(16) *North-West London Railway.*—This railway is to run under the Edgware Road to Cricklewood. The line was authorised in 1899, but construction work has not yet started. There are to be stations every half mile.

(17) *Great Northern and City Railway.*—An extension of this railway (which starts at Finsbury Park) to the Bank has been granted. The construction work is nearly completed. The generating station is to be on the Regent's Canal (7).

(18) *City and Brixton Railway.*—This line, which has been leased to the City and South London Railway, runs under the Brixton Road and connects Brixton with the City. Construction work has not yet commenced and details are not available.

(19) *London, Tilbury and Southend Railway.*—Powers have been granted to run the whole of this line electrically, but it is not proposed to do so until necessary. At first only such portions will be converted as are considered necessary to work in with the District Railway electrification. A site, large enough for a generating station for the whole line, has been acquired on the River Roding (a little beyond the limit of the map).

M. S.

THE PITTSBURG MEETING OF THE AMERICAN ASSOCIATION.

THE fifty-first annual meeting of the American Association for the Advancement of Science was held at Pittsburg, Pa., June 28–July 3, 1902, under the presidency of Prof. Asaph Hall, formerly of the United States Naval Observatory, and Harvard University.

The meeting was not a large one, but was attended by many of the leading men of science in the United States. The total registration was 436, and the majority of those in attendance were Fellows. A number of affiliated societies met at the same time and place in connection with the Association. These societies were the Geological Society of America, the American Chemical Society, the Society for the Promotion of Agricultural Science, the Botanical Society of America, the American Microscopical Society, the American Folk-Lore Society, the Association of Economic Entomologists, the Society for the Promotion of Engineering Education, the American Physical Society, the American Anthropological Association and the National Geographic Society. The meetings of these societies were all largely attended and their registration was not included in that of the Association, so that the Pittsburg meeting was practically a gathering of about one thousand scientific men.

As is quite natural, on account of its great mining and manufacturing interests, Pittsburg proved to be an especially attractive meeting-place for the engineers and geologists. The botanical and chemical sections and their affiliated societies were also represented with especial strength.

The address of the retiring president, Dr. Charles Sedgwick Minot, of the Harvard Medical School, was delivered on the evening of July 1 and is printed in full in this number. The other evening functions of the meeting were :—(1) A popular lecture by Dr. Leonard P. Kinnicutt, of the Worcester Polytechnic Institute, on "The Prevention of the Pollution of Streams by Modern Methods of Sewage Treatment." Dr. Kinnicutt is a well-known American expert in this line of work, and has been a careful observer of the experiments which have been and are being made in England, many of his lantern slides referring to English work. (2) On July 3 Mr. Robert T. Hill, of the U.S Geological Survey, gave an illustrated lecture on the recent volcanic eruptions in Martinique. Mr. Hill was leader of an expedition to Martinique a few days after the eruption of Mont Pelée, other members being Prof. I. C. Russell, of Ann Arbor, Mich., and Commander Borchgrevink. The expedition was sent out by the National Geographic Society.

The vice-presidential addresses were as follows :—

Prof. James McMahon, of Cornell University, before the Section of Mathematics and Astronomy, on the subject "Some Recent Applications of the Function Theory to Physical Problems." Prof. D. B Brace, of the University of Nebraska, before the Section of Physics, on the subject "The Group Velocity and the Wave Velocity of Light." Prof. H. S. Jacoby, of Cornell University, before the Section of Mechanical Science and Engineering, on the subject "Recent Progress in American Bridge Construction." Dr. B. T. Galloway, of the U.S. Department of Agriculture, before the Section of Botany, on

the subject "Applied Botany—Retrospective and Prospective." Prof. C. R. Van Hise, of the University of Wisconsin, before the Section of Geology and Geography, on the subject "The Training and Work of a Geologist." Prof. David Starr Jordan, of Stanford University, before the Section of Zoology, on the subject "The History of Ichthyology." Dr. J. Walter Fewkes, of the Bureau of American Ethnology, before the Section of Anthropology, on the subject "Prehistoric Porto Rico." Mr. John Hyde, of the U.S. Department of Agriculture, before the Section of Social and Economic Science, on the subject "Some Statistical and Economic Aspects of Preventable Diseases."

Certain important amendments to the constitution were made. The terms of office of secretaries of sections were lengthened from one year to five years. The council was given the power to add to its number nine Fellows whose terms of office shall be three years. The sectional committees were given greater permanency by provision for the election of one member each year who shall serve five years. All the recent changes in the constitution have aimed towards a greater permanency in the executive officers of the Association, of the council and of the sectional committees, and have increased the powers of the council.

The report of the treasurer and the financial report of the permanent secretary show the finances of the Association to be in a prosperous condition, and although they have by no means reached the standing of those of the British Association, the American Association is able this year to devote more funds to research grants. This year grants were made to committees on anthropometric measurements, the study of blind vertebrates, the relations of plants and climate, the atomic weight of thorium, and the determination of the velocity of light.

The next meeting of the Association will be held at Washington, from December 29, 1902, to January 3, 1903. The change in the time of meeting is a very important one and was made only after the most careful consideration. American universities and colleges have lengthened their Christmas holidays so as to enable the members of the scientific faculties to attend such winter meetings, and the week which contains the first day of January each year has been designated as "Convocation Week." Not only will the national scientific societies of the United States meet during this week under the auspices of the American Association, but the other learned societies of the country will also adopt this plan.

The president elected for the Washington meeting is Prof. Ira Remsen, the well-known chemist, recently made president of Johns Hopkins University. The vice-presidents of the different sections will be as follows:—Mathematics and Astronomy, Prof. George Bruce Halsted, of the University of Texas; Physics, Prof. E. F. Nichols, of Dartmouth College; Chemistry, Prof. Charles Baskerville, of the University of North Carolina; Mechanical Science and Engineering, Prof. C. A. Waldo, of Purdue University; Geology and Geography, Prof. W. M. Davis, of Harvard University; Zoology, Prof. C. W. Hargitt, of Syracuse University; Botany, Mr. F. V. Coville, of the U. S. Department of Agriculture; Anthropology, Mr. G. M. Dorsey, of the Field Columbian Museum, Chicago; Social and Economic Science, Mr. H. T. Newcomb, of Philadelphia, editor of *The Railway World*.

At the Washington meeting many additional societies will come into affiliation with the American Association, notably the American Society of Naturalists, with its group of special societies which have always held a mid-winter meeting, namely, the Society of Morphologists, the Society of Anatomists, the Society of Physiologists, the Society of Psychologists, the Society of Bacteriologists, the Society of Plant Morphologists, and others.

ADDRESS BY PROF. C. S. MINOT, PRESIDENT OF THE ASSOCIATION.

The Problem of Consciousness in its Biological Aspects.

OUR Association meets in Pittsburg for the first time. We are glad to indicate by our assembling here our appreciation of the immense work for the promotion of education and science which has been begun in this city and already is of national value. It has been initiated with so great wisdom and zeal that we expect it to render services to knowledge of the highest character, and we are glad to be the guests of a city and of institutions which are contributing so nobly to the cause of science.

We may congratulate ourselves on the bright prospects of the Association. Our membership has grown rapidly, and ought soon to exceed four thousand. Every member should endeavour to secure new adherents. For our next meeting we are to break with the long tradition of summer gatherings and assemble instead at New Year's time, presumably at Washington. To render this possible it was necessary to secure the cooperation of our universities, colleges and technical schools to set aside the week in which the first of January falls as "Convocation Week" for the meetings of learned societies. The plan, owing to the cordial and almost universal support given by the higher educational institutions, has been successfully carried through. For the winter meetings we have, further, succeeded in securing the cooperation of numerous national societies. The change in our time of meeting is an experiment, which we venture upon with the greater confidence because of the success of our present meeting in Pittsburg.

For my address this evening I have chosen the theme, "The Problem of Consciousness in its Biological Aspects." I hope both to convince you that the time has come to take up consciousness as a strictly biological problem, and also to indicate the nature of that problem and some of the actual opportunities for investigating it. It is necessary to begin with a few words on the philosophical interpretation. We shall then describe the function of consciousness in animal life, and consider its part in the evolution of animals and of man. The views to be stated suggest certain practical recommendations, after presenting which I shall conclude by offering an hypothesis of the relation of consciousness to matter and force.

Consciousness is at once the oldest problem of philosophy and one of the youngest problems of science. The time is not yet for giving a satisfactory definition of consciousness, and we must fain content ourselves with the decision of the metaphysician, who postulates consciousness as an ultimate datum or concept of thought, making the brief dictum *cogito, ergo sum* the pivot about which his system revolves. I have endeavoured vainly to discover, by reading and by questioning those philosophers and psychologists whom I know, some deeper analysis of consciousness, if possible, resolving it into something more ultimate.

Opinions concerning consciousness are many, and often so diverse as to be mutually exclusive, but they may be divided into two principal classes. The first class includes all those views which make of consciousness a real phenomenon, the second those views which interpret it as an epiphenomenon. We are, I think, practically all agreed that the fundamental question is, Does or does not consciousness affect directly the course of events? Or stated in other words, Is consciousness a true cause? In short, we encounter at the outset the problem of free-will, of which more later.

The opinion that consciousness is an epiphenomenon has gained renewed prominence in recent times, for it is, so to speak, a collateral result of that great movement of European thought which has culminated in the development of the doctrine of monism. Monism itself is postulated chiefly upon the two greatest discoveries of the nineteenth century, the law of the conservation of energy and the law of the evolution of species. Both laws establish a greater unity in the phenomena of the universe than mankind had previously been able to accept. In the physical world, instead of many forces we now recognise only one force,[1] which assumes various forms of energy, and in the living world we recognise one life, which manifests itself in many types of form. With these two unities in mind, what could be nearer than the thought that the unity goes still deeper,

[1] Force is used throughout this address as more likely to be understood by a general audience. It would be more correct to use "energy" in the sense in which the word is now applied technically in physics.

and that the phenomena of the inanimate or physical and of the living world are fundamentally identical? The progress of physiological science has greatly increased the impetus towards the adoption of this thought as the cardinal dogma of the new faith, because the work of physiologists has been so devoted to the physical and chemical phenomena of life that the conviction is widespread that all vital phenomena are capable of a physical explanation. Assuming that conviction to be correct, it is easy to draw the final conclusion that the physical explanation suffices for the entire universe. As to what is, or may be, behind the physical explanation, complete agnosticism is, of course, the only possible attitude. Such in barest, but I believe correct, outline is the history of modern monism, the doctrine that there is but one kind of power in the universe.

It is evident that monism involves the elimination of two concepts, God and consciousness. It is true that monists sometimes use these words, but it is mere jugglery, for they deny the concepts for which the words actually stand. Now consciousness is too familiar to all men to be summarily cast aside and dismissed. Some way must be found to account for it. From the monistic standpoint there is a choice between two possible alternatives, either consciousness is a form of energy, like heat, &c., or it is merely a so-called epiphenomenon. As there is no evidence that consciousness is a form of energy, only the second alternative is in reality available, and in fact has been adopted by the monists.

It is essential to have a clear notion of what is meant by an epiphenomenon. Etymologically the word indicates something which is superimposed upon the actual phenomenon. It designates an accompanying incident of a process, which is assumed to have no causal relation to the further development of the process. In practice it is used chiefly in regard to the relation of the mind or consciousness to the body, and is commonly employed by those philosophers who believe that consciousness has no causal relation to any subsequent physiological process.

For many years I have tried to recognise some actual idea underneath the epiphenomenon hypothesis of consciousness, but it more and more seems clear to me that there is no idea at all, and that the hypothesis is an empty phrase, a subterfuge, which really amounts only to this: we can explain consciousness very easily by merely assuming that it does not require to be explained at all. Is not that really the confession made by the famous assertion that the consciousness of the brain no more requires explanation than the aquosity of water?

Monism is not a strong system of philosophy, for it is not so much the product of deep and original thinking as the result of a contemporary tendency. It is not the inevitable end of a logical process, because it omits consciousness, but rather an incidental result of an intellectual impulse. Its very popularity betokens its lack of profundity, and its delight in simple formulæ is characteristic of that mediocrity of thought which has much more ambition than real power and accepts simplicity of formularisation as equivalent to evidence. It would seem stronger, too, if it were less defended as a faith. Strong partisans make feeble philosophers.

Consciousness ought to be regarded as a biological phenomenon, which the biologist has to investigate in order to increase the number of verifiable data concerning it. In that way rather than by speculative thought is the problem of consciousness to be solved, and it is precisely because biologists are beginning to study consciousness that it is becoming, as I said in opening, the newest problem of science.

The biologist must necessarily become more and more the supreme arbiter of all science and philosophy, for human knowledge is itself a biological function, which will become comprehensible just in the measure that biology progresses and brings knowledge of man, both by himself and through comparison with all other living things. We must look to biologists for the mighty generalisations to come rather than to the philosophers, because great new thoughts are generated more by the accumulation of observations than by deep meditation. To know, observe. Observe more and more, and in the end you will know. A generalisation is a mountain of observations; from the summit the outlook is broad; the great observer climbs to the outlook while the mere thinker struggles to imagine it. The best that can be achieved by sheer thinking on the data of ordinary human experience we have already as our glorious inheritance. The principal contribution of science to human progress is the recognition of the value of accumulating data, which are found outside of ordinary human experience.

Twenty-three years ago, at Saratoga, I presented before the meeting of this Association—which I then attended for the first time—a paper "On the Conditions to be Filled by a Theory of Life," in which I maintained that before we can form a theory of life we must settle what are the phenomena to be explained by it. So now, in regard to consciousness, it may be maintained that for the present it is more important to seek additional positive knowledge than to hunt for ultimate interpretations. We welcome, therefore, especially the young science of experimental psychology, which, it is gratifying to note, has made a more auspicious start in America than in any other country. It completes the circle of the biological sciences. It is the department of biology to which properly belongs the problem of consciousness. The results of experimental psychology are still for the most part future. But I shall endeavour to show that we may obtain some valuable preliminary notions concerning consciousness from our present biological knowledge.

We must begin by accepting the direct evidence of our own consciousness as furnishing the basis. We must, further, accept the evidence that consciousness exists in other men essentially identical with the consciousness in each of us. The anatomical, physiological and psychological evidence of the identity of the phenomena in different human individuals is to a scientific mind absolutely conclusive, even though we continue to admit cheerfully that the epistemologist rightly asserts that no knowledge is absolute, and that the metaphysician rightly claims that *ego* is the only reality and everything else exists only as *ego's* idea, because in science, as in practical life, we assume that our knowledge is real and is objective in source.

For the purposes of the following discussion we must define certain qualities or characteristics of consciousness. The most striking distinction of the processes in living bodies, as compared with those in inanimate bodies, is that the living processes have an object—they are teleological. The distinction is so conspicuous that the biologist can very often say *why* a given structure exists or *why* a given function is performed, but *how* the structure exists or *how* the function is performed he can tell very imperfectly—more often not at all. Consciousness is only a particular example, though an excellent one, of this peculiarity of biological knowledge; we do not know what it is; we do not know how it functions; but we do know why it exists. Those who are baffled by the elusiveness of consciousness, when we attempt to analyse it, will do well to remember that all other vital phenomena are in the last instance equally and similarly elusive.

In order to determine the teleological value of consciousness we must endeavour to make clear to ourselves what the essential function is which it performs. As I have found no description or statement of that function which satisfied me, I have ventured, perhaps rashly, to draw up the following new description:—

The function of consciousness is to dislocate in time the reactions from sensations.

In one sense this may be called a definition of consciousness, but inasmuch as it does not tell what consciousness is, but only what it does, we have not a true definition, but a description of a function. The description itself calls for a brief explanation. We receive constantly numerous sensations, and in response to these we do many things. These doings are, comprehensively speaking, our reactions to our sensations. When the response to a stimulus is obviously direct and immediate, we call the response a reflex action; but a very large share of our actions are not reflex, but are determined in a far more complicated manner by the intervention of consciousness, which may do one of two things, first, stop a reaction, as, for example, when something occurs calling, as it were, for our attention and we do not give our attention to it; this we call conscious inhibition; it plays a great *rôle* in our lives, but it does not mean necessarily that inhibited impressions may not survive in memory and at a later time determine the action taken; in such cases the potential reaction is stored up. Second, consciousness may evoke a reaction from a remembered sensation and combine it with sensations received at other times. In other words, consciousness has a selective power, manifest both in choosing from sensations received at the same time and in combining sensations received at different times. It can make synchronous impressions dyschronous in their effects, and dyschronous impressions synchronous. But this somewhat formidable sentence merely paraphrases our original description:—The function of consciousness is to dislocate in time the reactions from sensations.

This disarrangement and constant rearrangement of the sensations, or impressions from sensations, which we gather, so that their connections in time are altered, seems to me the most fundamental and essential characteristic of consciousness which we know. It is not improbable that hereafter it will become possible to give a better characterisation of consciousness. In that case the opinion just given may become unsatisfactory and have to yield to one based on greater knowledge. The characteristic we are considering is certainly important, and so far as the available evidence goes it belongs exclusively to consciousness. Without it life would have no interest, for there would be no possibility of experience, no possibility of education.

Now the more we have learned about animals, the better have we appreciated the fact that in them only such structures and functions are preserved as are useful or have a teleological value. Formerly a good many organs were called rudimentary or vestigial, and were supposed to be useless survivals because they had no known function. But in many cases the functions have since been discovered. Such, for example, were the pineal gland, the pituitary body, the suprarenal capsules and the Wolffian body of man, all of which are now recognised to be functionally important structures. Useless structures are so rare that one questions whether any exist at all, except on an almost insignificant scale. It has accordingly become well-nigh impossible for us to imagine consciousness to have been evolved, as it has been, unless it had been bionomically useful. Let us, therefore, next consider the value of consciousness from the standpoint of bionomics.[1]

We must begin with a consideration of the nature of sensations and the object of the reactions which they cause. In the simpler forms of nervous action a force, usually, but not necessarily, external to the organism, acts as a stimulus, which causes an irritation; the irritation produces a reaction. Within the ordinary range of the stimuli to which an organism is subjected the reaction is teleological—that is, it tends to the benefit of the organism. A familiar illustration is the presence of food in the stomach, which produces a stimulus, the reaction to which is manifested by the secretion of the digestive fluid for the purpose of digesting the food. An organism might conceivably be maintained solely by this mechanism, in cooperation with the physical laws, which govern all matter. Life in such an organism would be a succession of teleological processes, essentially mechanical and regulated automatically by the organism. By far the majority of biologists regard plants as essentially conforming to this type of life. Whether they absolutely so conform we do not, of course, yet know.

A sensation involves the interpolation of consciousness between the stimulation and the reaction, and in consequence there is established the possibility of a higher order of adjustment to the external world than can be attained through the teleological reaction to a stimulus. This possibility depends upon the fact that the intervention of consciousness permits an adjustment in accordance, not merely with the immediate sensation, but also and at the same time in accordance with earlier sensations. Thus, for example, the child sees an object, and its reaction is to take hold of the object, which is hot and hurts the child. Later the child sees the object again, and its natural reaction is to take hold of it again; but the child now reacts differently because its consciousness utilises the earlier as well as the present sensation; the previous sensation is dislocated in time and fused with the present sensation, and a new reaction follows. No argument is necessary to establish the obvious conclusion that an organism which has consciousness has an immensely increased scope for its adjustments to the external conditions; in other words, consciousness has a very high value for the organism. It is unnecessary to dwell upon this conclusion, for it will be admitted by everyone, except, perhaps, those who start with the *a priori* conviction that consciousness is an epiphenomenon.

A sensation gives information concerning the external world. Perhaps science has achieved nothing else which has done so much to clarify philosophy as the demonstration that the objective phenomena are wholly unlike the subjective sensations. Light is a series of undulations, but we do not perceive the undulations as such, but as red, yellow and green, or, as we say, colours; the colours give us available information, and we use them as so many labels, and we learn that reactions to these labels may be helpful or hurtful, and so we regulate our conduct. Objectively red, yellow and green do not exist. Similarly with the vibrations of the air, certain of which cause the sensation of sound, which is purely subjective. But the sound gives us information concerning our surroundings which we utilise for our teleological needs, although in nature, external to us, there is no sound at all. Similarly, all our other senses report to us circumstances and conditions, but always the report is unlike the external reality. Our sensations are symbols merely, not images. They are, however, bionomically sufficient because they are constant. They are useful, not because they copy the external reality or represent it, but because, being constant results of external causes, they enable consciousness to prophesy or foresee the results of the reactions of the organism, and to maintain and improve the continual adjustment to the external reality.

The metaphysicians have for centuries debated whether there is any external objective reality. Is it too much to say that the biological study of consciousness settles the debate in favour of the view that the objective world is real?

Consciousness is not only screened from the objective world from which it receives all its sensations, but also equally from immediate knowledge of the body, through which it acts. As I write this sentence I utilise vaso-motor nerves, regulating the cerebral blood currents, and other nerves, which make my hand muscles contract and relax, but of all this physiological work my consciousness knows nothing, though it commands the work to be done. The contents of consciousness are as unlike what is borne out from it as they are unlike what is borne in to it.

The peculiar untruthfulness to the objective, which consciousness exhibits in what it gets and gives, would be perplexing were it not that we have learned to recognise in consciousness a device to secure better adjustment to external reality. For this service the system of symbols is successful, and we have no ground for supposing that the service would be better if consciousness possessed direct images or copies instead of symbols of the objective world.

Our sensory and motor[1] organs are the servants of consciousness, its messengers or scouts, its agents or labourers, and the nervous system is its administrative office. A large part of our anatomical characteristics exists for the purpose of increasing the resources of consciousness, so that it may do its bionomic function with greater efficiency. Our eyes, ears, taste, &c., are valuable because they supply consciousness with data; our nerves, muscles, bones, &c., are valuable because they enable consciousness to effect the needed reactions.

Let us now turn our attention to the problem of consciousness in animals. The comparative method has an importance in biology which it has in no other science, for life exists in many forms, which we commonly call species. Species, as I once heard it stated, differ from one another with resemblance. The difference which resembles we term an homology. Our arm, the bird's wing, the lizard's front leg are homologous. The conception of homology, both of structure and of function, lies at the basis of all biological science, which must be and remain incomprehensible to any mind not thoroughly imbued with this conception. Only those who are deficient in this respect can fail to understand that the evidence is overwhelming that animals have a consciousness homologous with the human consciousness. The proof is conclusive. As regards at least mammals, I think we could safely say as regards vertebrates, the proof is the whole sum of our knowledge of the structure, functions and life of these animals.

As we descend the animal scale to lower forms there is no break, and therefore no point, in the descent where we can say, here animal consciousness ends and animals below are without it. It seems inevitable, therefore, to admit that consciousness extends far down through the animal kingdom, certainly at least as far down as there are animals with sense organs or even the most rudimentary nervous system. It is unsatisfactory to rely chiefly on the anatomical evidence for the answer to our query. We await eagerly results from psychological experiments on the lower invertebrates. A sense organ, however, implies consciousness, and since such organs occur among cœlenterates we are led to assign consciousness to these animals.

The series of considerations which we have had before us lead directly to the conclusion that the development and improvement of consciousness has been the most important—really the dominant—factor in the evolution of the animal series. The

[1] A convenient term, recently gaining favour, for what might otherwise be called the economics of the living organism. Bionomics seems preferable to *ecology*, which some writers are adopting from the German.

[1] And other organs in efferent relations to consciousness.

sense organs have been multiplied and perfected in order to supply consciousness with a richer, more varied and more trustworthy store of symbols, corresponding to external conditions. The nervous system has grown vastly in complexity in order to permit a constantly increasing variety in the time dislocations of sensations. The motor and allied apparatus have been multiplied and perfected in order to supply consciousness with more possibilities of adjustment to external reality, which might be advantageous.

If we thus assign to consciousness the leading *rôle* in animal evolution we must supplement our hypothesis by another, namely, that conscious actions are primary, reflex and instinctive actions secondary; or in other words, that for the benefit of the organism conscious actions have been transformed into reflexes and instincts. Unfortunately, we must rely chiefly on future physiological and psychological experiments to determine the truth of this hypothesis. Its verification, however, is suggested by certain facts in the comparative physiology of the vertebrate nervous system, which tend to show that in the lower forms (amphibia) a certain degree of consciousness presides over the functions of the spinal cord which in mammals is devoted to reflex actions. Its verification is further suggested by the natural history of habits. As we all know, new actions are performed with difficulty, and slowly, but if often repeated they are soon easier and more rapid. If a given reaction to a sensation or group of sensations through consciousness is advantageous to the organism, and the environment is such that the sensation is often repeated, then a habit is formed, and the response becomes more rapid; and often in ourselves we see habits, which arose from conscious action, working almost without the participation of consciousness, and moreover working usefully, because rapidly. The usefulness of conscious reactions is that they are determined, not merely by the present sensation, but also by past sensations; but they have the defect that they are slow. We can readily understand that it would aid an organism to have the quicker reaction substituted, and we thus recognise a valid teleological reason for the replacement of conscious action by habits in the individual, by instincts in the race. The investigation of the evolution of reflexes and instincts is one of the important and most promising tasks of comparative psychology.

A frank, unbiassed study of consciousness must convince every biologist that it is one of the fundamental phenomena of at least animal life, if not, as is quite possible, of all life. Nevertheless its consideration has barely a place in biological science, although it has long occupied a vast place in philosophy and metaphysics. If this address should contribute to a clearer appreciation of the necessity of treating consciousness as primarily a problem for biological research to solve, my purpose will be achieved. In an ideal world philosophers and men of science would be identical; in the actual world there are philosophical men of science and scientific philosophers; but in the main the followers of the two disciplines pursue paths which are, unfortunately, distinct. The philosophical mind is of a type unlike the scientific mind. The former tries to progress primarily by thought based on the data available, the latter seeks to advance primarily by collecting additional data. The consequence of this difference is that philosophy is dependent upon the progress of science, but we who pursue the scientific way can make no greater mistake than to underestimate philosophy. The warning is needed. Data of observation are a treasure and very precious. They are the foundation of our mental wealth, but that wealth consists of the thought into which the data are transmuted. In pleading, therefore, for an increased observational study of consciousness we plead, not merely for science, but equally for philosophy. The scientific progress must come first. Hence we urge the advantage of investigating consciousness in its immediate revelations, which are accessible now. Let us give up the ineffectual struggle to discover the essential nature of consciousness until we can renew it with much larger resources of knowledge.

The psychologists ought now to apply the comparative method on a grand scale. They are just beginning to use it. Years of patient labour must pass by, but the reward will be very great. The psychic life of animals must be minutely observed, the conditions of observation carefully regulated, and the results recorded item by item. The time has passed by for making generalisations on the basis of our common, vague and often inexact notions concerning the habits of animals. Exact experimental evidence will furnish a rich crop of psychological discovery. Scientific psychology is the most backward in its development of all the great divisions of biology. It needs, however, little courage to prophesy that it will bring forth results of momentous importance to mankind. After data have been gathered, generalisations will follow which, it may be hoped, will lead us on to the understanding of even consciousness itself.

The teleological impress is stamped on all life. Vital functions have a purpose. The purpose is always the maintenance of the individual or of the race in its environment. The entire evolution of plants and animals is essentially the evolution of the means of adjustment of the organism to external conditions. According to the views I have laid before you, consciousness is a conspicuous, a commanding factor of adjustment in animals. Its superiority is so great that it has been, so to speak, eagerly seized upon by natural selection and provided with constantly improved instruments to work with. A concrete illustration will render the conception clearer. In the lowest animals, the cœlenterates, in which we can recognise sense organs, the structure of them is very simple, and they serve as organs of touch and of chemical sensation resembling taste. In certain jelly fishes we find added special organs of orientation and pigmented spots for the perception of light. In worms we have true eyes and vision. In vertebrates we encounter the true sense of smell. Fishes cannot hear, but in the higher vertebrates, that is from the amphibians up, there are true auditory organs. In short, both the senses once evolved are improved and also new senses are added. It is perfectly conceivable that there should be yet other senses, radically different from any we know. Another illustration, and equally forcible, of the evolution of aids to consciousness might be drawn from the comparative history of the motor systems, passing from the simple contractile thread to the striated muscle fibre, from the primitive diffuse nunculature of a hydroid to the highly specialised and correlated muscles of a mammal.

It is interesting to consider the evolution of adjustment to external reality in its broadest features. In the lowest animals the range of the possible adjustment is very limited. In them, not only is the variety of possible actions small, but they cover also a small period of time. In animals which have acquired a higher organisation, the adjustments are more complex both because the reactions are more varied and because they cover a longer period of time. Thus the jelly fish depends upon such food as happens to come within its reach, seizing from moment to moment that which it encounters; but a lobster pursues its food, making complicated movements in order to reach and seize it. One can trap lobsters easily; I doubt if one could trap a jelly fish at all. The next great advance is marked by the establishment of communication between individuals of the same species. About this phenomenon we know exceedingly little; the investigation of it is one of the most important duties of the comparative physiologist. Its bionomic value is obviously great, for it allows an individual to utilise the experience of another as well as its own. We might, indeed, compare it with the addition of a new sense, so greatly does it extend the sources of information. The communication between individuals is especially characteristic of vertebrates, and in the higher members of that subkingdom it plays a very great *rôle* in aiding the work of consciousness. In man, owing to articulate speech, the factor of communication has acquired a maximum importance. The value of language, our principal medium of communication, lies in its aiding the adjustment of the individual and the race to external reality. Human evolution is the continuation of animal evolution, and in both the dominant factor has been the increase of the resources available for consciousness.

In practical life it is convenient to distinguish the works of nature from the works of man, the "natural" from the "artificial." The biologist, on the contrary, must never allow himself to forget that man is a part of nature and that all his works are natural works. This is specially important for the present discussion, for otherwise we are likely to forget also that man is as completely subject to the necessity of adjustment to external reality as any other organism. From the biological standpoint, all the work of agriculture, of manufactures, of commerce and of government is a part of the work of consciousness to secure the needed adjustments. All science belongs to the same category as the teleological efforts of a jelly fish or lobster. It is work done at the command of consciousness to satisfy the needs of existence. The lesson of all this to us is that we should accustom ourselves to profit by our understanding of the trend of evolution, which, in the progress humanity makes, obeys the

same law of adaptation to objective reality which has controlled the history of animals. This view of the conditions of our existence puts science in its right place. As all sensations are symbols of external reality useful to guide organisms to teleological reactions, so is all science symbolic and similarly useful.

Nature never produces what to us seems a perfect organism, but only organisms which are provided with means of adjustment sufficient to accomplish the survival and perpetuation of the species. Man also is imperfect, but in the struggle for existence wins his way because his consciousness has greater resources than that of any other organism. His great power arises from his appreciation of evolution. His highest duty is to advance evolution, and this duty must be most strongly felt by those who accept the religious interpretation of life. The advancement of science is an obligation. To this view of the work of our Association I may safely claim the assent of all present.

The function of science is to extend our acquaintance with the objective world. The purpose of the American Association is not alone to increase the sum total of science, but equally also to preach by word and precept the value of truth, truth being the correct conscious symbol of the objective, by utilising which our purposeful reactions are improved. The most serious obstacle truth encounters is the prevalence of what I may call "doll ideas," by analogy with the material dolls with which children play. The child "makes believe" with the doll, knowing all the time its unreality, assigns to it hopes, passions, appetites; the child may feel the intensest sympathy with its doll, weep at its sorrows, laugh over its joys, yet know always that it is a mere inanimate, senseless doll. Adult men and women have ideas, with which they play make-believe; doll ideas, which they know are unreal, and yet they mourn sincerely over the adversities of their mental dolls, rejoice over their successes and fight for them with passion. Such doll ideas become mingled with the real and inextricably woven into the fabric of life. They are treated with the most earnest seriousness. Men will fight for them as a child will fight for its doll, not because it is property, but because it is sacred personality. So are doll ideas often made sacred and defended with fanaticism. Yet behind, in consciousness, is the sense of unreality, the disregarded admission of "making believe." Do not doll-ideas—pseudo-opinions—play a great *rôle* in human life? I think they do, and thinking so, deem it all the more imperative that you and others should teach the people the standard of science, the humble acknowledgment of reality. I wish an impulse towards this goal from our Association could be imparted to every man and woman in the country, and I hope the Association may continue to grow in number and power for long years to come, as it has grown in the last few years, so that it shall be a national, all-pervading influence serving the truth.

It seems to me inconceivable that the evolution of animals should have taken place as it actually has taken place, unless consciousness is a real factor and dominant. Accordingly, I hold that it actually affects the vital processes. There is, in my opinion, no possibility of avoiding the conclusion that consciousness stands in immediate causal relations with physiological processes. To say this is to abide by the facts, as at present known to us, and with the facts our conceptions must be made to accord.

The thought which I wish to emphasise is the importance for the future investigation of consciousness of separating the study of what it does from the study of what it is. The latter study is recondite, metaphysical, and carries us far beyond the limits of verifiable human knowledge. The former study is open to us and offers opportunities to science, but it has hitherto been almost completely neglected. Biology has now to redeem itself by effectual researches on consciousness. On the adequate prosecution of such researches we base great hopes.

Before I close, permit me a few words concerning the relations of consciousness to the body, to the living substance through which it manifests itself. It is intimately linked to protoplasm. Probably no question is so profoundly interesting to all mankind as the old question, What is the relation of the mind to the body? It is a question which has been stated in many forms and from many points of view, but the essential object of the question is always the same, to ask whether consciousness is a function of living matter or something discrete and not physical or material.

Throughout this address consciousness has been viewed as a device to regulate the actions of the organism so as to accomplish purposes which on the whole are useful to the organism, and accordingly we have termed its function teleological. If this view is correct, it accounts for the limitations of consciousness, its mechanical mode of work, its precision and definiteness of action, for, of course, unless consciousness is orderly and obeys laws it cannot be of use to the organism, but, on the contrary, it would be harmful, and conscious animals would have ceased long ago to survive. The very fact that consciousness is of such high value in the bionomy of an animal renders it obvious that it must be subject to law. Accordingly it appears to us regulated as do the functions of protoplasm, hence to certain modern thinkers it presents itself as a function of protoplasm, or, as it may be better stated, as a state or condition of protoplasm.

The internal evidence of consciousness, however, is against this view and presents to us conscious actions as depending upon the consciousness. As before stated, I believe this evidence must be accepted. Now all the sensations of consciousness are derived from physical force, and all the acts of consciousness are manifested through physical force, hence if it has any real power consciousness must be able to change the form of energy. Unless we accept this doctrine we must give up all belief in free-will and adopt the automaton theory of life. Is not the more reasonable explanation that which is based upon all the contents of our consciousness rather than that which we can draw only by discarding the internal evidence which consciousness brings us? The hypothesis which I offer for your consideration is this:—

Consciousness has the power to change the form of energy, and is neither a form of energy nor a state of protoplasm.

By this hypothesis there are two fundamentally different things in the universe—force and consciousness. You ask why I do not say three, and add matter? My answer is that we do not have, and never have had, any evidence whatever that matter exists. All our sensations are caused by force, and by force only, so that the biologist can say that our senses bring no evidence of matter. The concept "matter" is an irrational transfer of notions derived from the gross molar world of the senses to the molecular world. Faraday long ago pointed out that nothing was gained and much lost by the hypothesis of material atoms, and his position seems to me impregnable. It would be a great contribution to science to kill off the hypothesis of matter as distinct from force.

To conclude, the universe consists of force and consciousness. As consciousness by our hypothesis can initiate the change of the form of energy, it may be that without consciousness the universe would come to absolute rest. Since I close with a bold speculation, let my last words recall to you that my text is:—Investigate consciousness by comparative observation. Only from observation can we know. Correct, intelligent, exhaustive observation is our goal. When we reach it, human science will be completed.

NOTES.

WE understand from recent Queensland newspapers that it has been determined to abolish the Weather Bureau of that colony as from the 30th ult., and that the services of Mr. C. L. Wragge and his special staff have been dispensed with. In a letter addressed by the Premier of Queensland to the Federal Prime Minister it is pointed out that this apparently retrograde step is owing to the urgent necessity for reducing in every branch of the public service the estimates of expenditure of the State, and that it is one of the "most unfortunate" results of the large deficit in the revenue, brought about by drought and other causes. Prior to federation, the Weather Bureau formed part of the Post and Telegraph Department of Queensland, and all telegrams and correspondence passed free. But during the last fifteen months the Federal Government has charged for these communications at the rate of about 4000*l.* a year, which expense cannot be borne any longer by the Queensland Government. The Premier writes that he feels sure the States in general will welcome any reasonable suggestions for a continuance of the work of the Bureau under federal control; we may therefore hope that the existing instruments and stations will be utilised, as far as practicable, in the interest of meteoro-

logical science. Truly the Colonies are in this respect following the mother country, and we may soon expect the Empire, so active in neglecting science, to be the laughing stock of civilised peoples.

THE Copenhagen correspondent of the *Times* reports that the International Conference for Biological and Hydrographical Research, the object of which is to promote ocean research for fishery purposes, was opened there on July 22. Dr. Deuntzer, Danish Foreign Minister, welcomed the delegates, who represented Great Britain, Sweden, Norway, Finland, Russia, Holland, Germany and Denmark. In reply to Dr. Deuntzer's welcome, the British delegate, Sir Colin Scott-Moncrieff, expressed the thanks of the delegates, who, he declared, earnestly hoped that their labours would have fruitful results. Herr Herwig, the German delegate, was elected president of the conference.

IT is stated that Prof. Virchow, who is now staying at Harzburg, is obliged to keep to his room owing to general weakness. His condition is causing uneasiness among his friends.

THE *British Medical Journal* announces that the King of Italy has given 10,000 lire to the Italian Red Cross Society in aid of the campaign against malaria in the Campagna this season. Prof. Postempski will, as formerly, act as director of the medical service organised under the auspices of the Society.

MR. E. B. BAILEY has been appointed a geologist on the Geological Survey of Scotland.

THE death is announced of Prof. Gerhardt, the well-known authority on diseases of the lungs and children's diseases, at his estate of Damberg, in Baden. Prof. Gerhardt, who was born in 1833, held professorships at Jena, Würzburg and Berlin, and was the author of several important medical works.

MR. BENJAMIN MARTELL, whose death we regret to see announced, for more than thirty years played a prominent part in the many important changes which have taken place during that period in connection with the development of ship construction in this country. He was born in 1825, and trained at Portsmouth Dockyard, where he served his time as an apprentice. He joined Lloyd's Register Society in 1856, and in sixteen years, after serving the Society at several of the important shipbuilding centres in the country, was called to the position of chief surveyor, which he held until his retirement in 1899. The tables of freeboard prepared by Mr. Martell, and afterwards placed upon the Statute Book, represent the results of one of the many pieces of work which he successfully carried out for the good of the shipping community.

WE regret to announce the death of Prof. V. Safarik (Schafarik) at the mature age of seventy-three, which took place at Prague on July 2. Prof. Safarik became professor of chemistry in the Bohemian Polytechnicum in 1868. In 1882 he was appointed professor of chemistry in the Bohemian University and in 1892 professor of descriptive astronomy, from which post he retired in 1896. In the fifties and sixties of last century he published several papers in organic chemistry (specific volumes, vanadium, platino-cyanides, &c.), and his last chemical paper was on the constitution of natural silicates, in 1872. Later on he devoted himself to astronomical investigations, which he carried out in his private observatory, and his work on the surfaces of planets, variable stars, &c., is well known to astronomers. He was an adept at grinding and polishing metallic and glass mirrors for reflectors and in silvering the latter. He attended the Bradford meeting of the British Association in 1873, and from that time was often in communication with several leading British astronomers. Those who knew Prof. Safarik personally could not but admire his very wide, almost universal knowledge; indeed, he was one of the last polyhistorians of the Alexander Humboldt school, whose work he translated into the Bohemian language. He has left behind a long series of astronomical observations, which he was prevented by ill-health from publishing.

AT the meeting of the London County Council on Tuesday, the Technical Education Board reported the result of the inquiry by a special subcommittee of the Board as to the need and present provision for special training of an advanced kind in connection with the application of science (especially chemistry and electricity) to industry, and as to what, if any, developments are needed to secure efficient training in these subjects for senior county scholars and other advanced students who desire to qualify themselves to take leading positions in scientific industries. The report of the special subcommittee deals with matters which the Board points out are of great importance to the present and future prosperity of various English industries, notably some connected with London. The members of the special committee came, without a dissentient voice, to the conclusions (1) that England (and London in particular) has suffered the loss of certain industries and that others are in danger; (2) that this loss has been largely due to defective education, especially in the higher grades; and (3) that London is still seriously behind other cities, notably Berlin, in the provision for the higher grades of scientific training and research. The report was accepted, with the addition of the recommendation "that the Technical Education Board be instructed to report as to the steps it proposes to take in order to give practical effect to the suggestions contained in the report."

GRANTS in aid of the following researches were made at a recent meeting of the Board of Trustees of the Elizabeth Thompson Science Fund:—150 dollars to Prof. H. E. Crampton, Columbia University, New York, for experiments on variation and selection in Lepidoptera. 100 dollars to Dr. F. W. Bancroft, University of California, Berkeley, Cal., for experiments on the inheritance of acquired characters. 125 dollars to Dr. J. Weinzirl, University of New Mexico, Albuquerque, N. Mex., for investigation of the relation of climate to the cure of tuberculosis, it being agreed that if the work justifies it the same amount will be granted next year. 300 dollars to Prof. H. S. Grindley, University of Illinois, Urbana, Ill., for investigation of the proteids of flesh. 300 dollars to Dr. H. H. Field, Zürich, Switzerland, to aid the work of the concilium bibliographicum. 250 dollars to Prof. T. A. Jaggar, Harvard University, Cambridge, Mass., for experiments in dynamical geology, provided the secretary receives the necessary assurance that the work can be undertaken with reasonable promptitude. 50 dollars to Dr. E. O. Jordan, University of Chicago, Chicago, Ill., for the study of the bionomics of Anopheles. 300 dollars to Dr. E. Anding, München, Bavaria, to assist the publication of his work "Ueber die Bewegung der Sonne durch den Weltraum," but the grant is conditional upon other means being also secured by the author sufficient to accomplish the publication. 300 dollars to Prof. W. P. Bradley, Wesleyan University, Middletown, Conn., for investigations on matter in the critical state. 300 dollars to Prof. Hugo Kronecker, Bern, Switzerland, for assistance in preparing his physiological researches for publication. 300 dollars to Prof. W. Valentiner, Grossh. Sternwarte, Heidelberg, Germany, to continue the work of Grant No. 93 (observations on variable stars).

IT is reported that a storm of unusual violence, accompanied by torrential rain and a heavy hail shower, broke over the city of Kieff on July 20. A violent cyclone passed over Chalon-sur-Saône on July 15 between 6 p.m. and 7 p.m., blowing down

chimneys and trees and sinking several vessels on the River Saône.

WE learn from the *Times* that news has been received of a severe earthquake shock at Bandar Abbas on July 9. It commenced at half-past seven in the morning and lasted three or four minutes. All the chief buildings suffered. The Governor's house partly collapsed, while the Customs office was destroyed. The shocks continued in the Persian Gulf on July 9 and 10, and apparently proceeded from Kishm Island. Loud noises at Kishm were distinctly audible at Bandar Abbas. It is feared that the destruction at Kishm is considerable. No further information is available. A few years ago an earthquake at Kishm destroyed hundreds of people. The whole population of Bandar Abbas has flocked to the sea-beach for safety.

A MESSAGE from the Geneva correspondent of the *Daily Chronicle*, dated July 14, says:—A luminous haze has attended the sunsets lately, as if the whole of the west of Switzerland was on fire and the flames reflected in the sky. Swiss men of science attribute this to the presence of fine dust or ashes in the upper currents of air, and are of opinion that this dust has been carried across the Atlantic from Mont Pelée by air currents. This supposition is given support by the news that after a shower of rain at Frauenfeld, in Canton Thurgau, the ground was covered with a thin layer of ashes of greyish-blue colour.

A TELEGRAM from Kingstown, St. Vincent, states that on Thursday last, July 17, several shocks of earthquake were felt there, a terrific shock being experienced at a quarter to ten in the morning, accompanied by a loud rumbling explosive sound like thunder. The worst shock lasted only ten seconds. The shocks were probably caused by explosions of subterranean gas or steam. A few days ago it was reported that the saddle between the two craters of the Soufrière had collapsed, throwing thousands of cubic feet of sand, scoriæ and rock into the funnel of the Soufrière, thus blocking the throat of the crater. In consequence of this, it is suggested that the gas and steam, failing to find any outlet by the throat or funnel of the mountain, caused internal explosions and severe concussions. A *Times* message from St. Thomas states that a severe earthquake was felt in St. Vincent on July 22 at 1.15 in the morning. The shocks were local, and seem to have been confined to a certain area of which Kingstown and its vicinity were apparently the centre.

IT would seem to be the universal belief that volcanic ash has very fertilising qualities, and Prof. d'Albuquerque's contrary view, as a result of the first examination of the St. Vincent ash which fell at Barbados early in May last, was generally regarded with suspicion. The latest number of the West Indian *Agricultural News* contains an interesting paragraph on the subject. Analyses by different authorities in the West Indies and in England showed conclusively, as Prof. Harrison said, "that the volcanic dust was quite valueless as a manure—the value of the soluble constituents being about three cents." Owing to the copious rains that fell in Barbados mmediately after the dust, causing a sudden bursting of leaf and flower on plants that had previously been parched by drought, a popular idea was fostered that the dust was, more or less, of a fertilising character. It is believed, probably on good grounds, that it was useful in destroying the small black ants common in the island, and in drying up the egg-clusters of the moth-borer then on the leaves of the sugar-cane.

MR. H. HESKETH BELL, Administrator of Dominica, has a long letter in Tuesday's *Times*, in which he shows that the effects of the recent volcanic eruptions in Martinique and St. Vincent have been greatly exaggerated in many reports. No attempt is made to minimise the disaster, but only to show that the area involved in it is comparatively small. Even estimating the devastated area in Martinique at fifty square miles, there still remain more than 300 square miles in that island that are practically in exactly the same condition as they were in the day before the eruption. With the exception of the blasted triangle on the western slope of Pelée, the whole colony is still dotted with plantations, homesteads and villages. St. Vincent has also suffered, but there are still 43,000 colonists in the island. No other islands have been affected. Although, as has correctly been stated, many of the Leeward and Windward Islands possess craters and volcanic cones, there has so far not been in any of them the slightest sympathetic activity with the outbursts in Martinique and St. Vincent. The fall of volcanic dust that has been noticed in many of the islands has simply been a harmless phenomenon, and, so far as sympathetic volcanic agency may be concerned, it is said that the islands might just as well have been thousands of miles away from the affected craters. Dominica is in precisely the same prosperous condition that it was in the day before the eruptions at Martinique and St. Vincent. Although barely forty miles distant from Pelée and near enough for the inhabitants to hear the detonations, Mr. Bell says the island has been absolutely unaffected by the recent outburst. The hot springs and geysers have remained in their normal condition, and, with the exception of one slight shock of earthquake felt by a few persons, there has not been any seismic disturbance. Even the shower of powdered scoriæ that fell on May 11 was so slight that its presence could only be detected on the surface of palm-leaves and other large foliage.

A CORRESPONDENT sends us from Bath a drawing of a rathe curious development of a foxglove (digitalis). The plant represented was similar to any ordinary foxglove, with the exception that the terminal flower of each inflorescence was not a foxglove blossom, but a Canterbury bell (campanula). This flower, from an external view, looked like any normal Canterbury bell; the stamens, however, were eight in number and similar to those of the foxglove, while the pistil was somewhat like that common to the foxglove. A botanist to whom we submitted the drawing and description tells us he obtained a photograph of the same kind of flower some years ago, and upon inquiry he found that the anomaly is fairly frequent and well known. The combination of two flowers other than the foxglove and campanula, if it occurs, would, however, be worth recording. The specimen from which the photograph mentioned was taken grew in a semi-wild garden in Surrey not far from London.

THE use of oxygen inhalers in connection with high balloon ascents was mentioned last week (p. 279). On the occasion of the last Aëronautical Congress held at Berlin, a report on the inhalation of oxygen was presented, and the subject has also occupied the attention of the Société française de Navigation aérienne. The July number of the *Aëronautical Journal* contains a report of a lecture delivered by Dr. Süring before this Society upon his ascent with Dr. Berson on July 31, 1901, when the height of 10,800 metres was reached. It was pointed out that as to the physiological side of the question, on closely studying foreign and German ascents, three stages may be distinguished. During the first of these stages the excitement exceeds considerably the phenomena of height-sickness proper, resulting from want of oxygen. In such a state of excitement, one does not know, perhaps, the real state of the height-sickness, and this naturally becomes an exceedingly critical matter when the dangers of a mishap become imminent. The regrettable issue of the *Zenith* expedition in the year 1874 is no doubt to be traced to this, to a large extent at any rate. The second and more dangerous stage is that of confusion. By systematically inhaling oxygen, this state of excitement leading to confusion and imminently dangerous conduct can be warded off by

aëronauts of ordinarily cool disposition; whereas it is evident that a state of enervation with signs of relaxation cannot be completely prevented. Notes are illegibly written in the wrong place, the eyes refuse their services, the slightest exertion results in a dangerous weakness, and, finally, the whole organism falls a victim to an inevitable need for sleep. But, also these illnesses may yet be overcome to a certain extent if greater precautions are taken in future ascents, if the aëronaut avoids all exertions, all excitement, sleeps sufficiently, undergoes a still more systematic inhaling of oxygen, begins earlier with it and protects himself sufficiently against cold.

PERHAPS the most singular statement in the Meteorological Office pilot chart for the month of August is that relating to the appearance, early in July, of a fairly large ice floe, 40 feet by 15 feet and a foot out of water, off the west of Scotland, close inshore on the Treshnish Islands, on the west side of Mull, and only a few miles from Tobermory. From other sources it appears that the fishermen who saw it could not be mistaken, as they sailed within 20 feet of the floe. It was reported by independent observers on two days. There can be little doubt that it was the remains of one of the icebergs which had for some time been infesting the coast of Iceland, but it would be interesting to trace its movements southward. Off Mull it was travelling in a north-easterly direction, so it is reasonable to suppose that it had at first drifted southward outside the Hebrides before the northerly winds which prevailed so long earlier in the season. While we have had this quite exceptional circumstance on our side of the Atlantic, the ice record about the Newfoundland banks remains almost blank. Three or four observers report a berg in about 48° N., 49° W., and there was one in 42° 40′ N., 47° 30′ W. The strait of Belle Isle had been clear of ice until about the end of June, but early in July several bergs had drifted in past Belle Isle. There was, however, nothing like the usual quantity at this time of the year, and shipmasters appear to have seen nothing of the heavy ice of a month earlier, which was reported to block the approaches to the strait. This freedom from ice probably explains the excess in the temperature of the sea surface on the banks and over an extensive region eastward and westward during the month of May last, the results of which, derived from 4400 observations, are shown on an inset chart.

AN interesting review of recent work in wireless telegraphy is commenced in *L'Eclairage Électrique* for July 5. The article is by M. Turpain, himself a worker in this field. It is noteworthy that the author is unable to credit Mr. Marconi's having succeeded in signalling across the Atlantic, and attributes the signals received at Newfoundland to atmospheric effects. No reference to the later experiments on the *Philadelphia* is made. M. Turpain also quotes evidence to show that the successful solution of the syntony problem has not as yet been found by Mr. Marconi. Prof. Slaby's system and the experiments with a repeater made by M. Guarini are also described in this instalment.

THE *Journal de Physique* for June contains an article by M. Armagnat on the study of resonance by means of oscillographs. The paper deals with the subject both theoretically and experimentally. The method has been devised because the wave forms obtained by means of an oscillograph, or other wave-tracing instrument, are not accurate enough to allow of the harmonics being found by means of graphical analysis. Two oscillographs are used, one in series with a non-inductive resistance tracing the wave-form under examination; the other is in series with a variable self-induction and capacity which are altered until the different harmonics are resonated and traced on the screen. The paper is illustrated by some interesting curves obtained in this manner, one of which shows how the method may be used to measure the irregularities in the speed of an alternator.

IN the "Verhandelingen der Koninklijke Akademie van Wetenschappen te Amsterdam (Tweede Sectie)," Deel ix. pp. 1–12, Dr. P. H. Eykman has published an interesting paper describing a method for obtaining a Röntgen photograph of an internal part of the living body during the performance of a definite functional movement. The author applies the method to the investigation of the motion of the tongue, pharynx and larynx in swallowing. He fixes a contact on the Adam's apple, the motion of which closes the current which feeds the Röntgen tube at a perfectly definite moment during the motion. The motion has to be repeated 120 or 130 times with the contact in exactly the same position in order to obtain a distinct photograph. Other photographs of different phases of the motion are obtained by altering the position of the contact. The photographs are good considering the difficulties of the experiment and throw a welcome light on the position of the epiglottis and on the condition of the upper opening of the larynx during the act of deglutition.

ALCOHOL as a motive power has formed an interesting set of experiments in France at the present time, the object being to produce a home-made substitute for petrol, which all has to be imported. According to *Feilden's Magazine* for July the results obtained are of a satisfactory nature. both for the heavier and lighter types of cars, and it is stated that passenger cars driven by alcoholic traction have been proved to hold their own against those with petrol as a motive power. The price of alcohol at present is higher, but by the use of beetroot in its manufacture its market value has been greatly reduced. The experiments showed that the amount of alcohol consumed by the engines (which were designed to burn petrol) was 50 per cent. higher than that of petrol, but it is stated that with engines properly constructed to use the new motive power this difference would be greatly reduced, and should this be the case it will form a home-made motor-car spirit to replace the imported article. Attention is also directed to the ease with which it can be prepared from potatoes, and consequently, on account of its general utility for heating, lighting, &c., it would seem that an opportunity is open for Ireland to create a most important industry.

MR. M. L. SYKES has favoured us with a copy of his paper on the evolution of butterfly-scales, published in the *Report and Transactions* of the Manchester Microscopical Society for 1901. The illustrations show that the scales of butterflies which mimic other species are generally quite different in form from those of the species mimicked.

ACCORDING to a photograph, taken from a living example, of which a reproduction is given by Dr. Jentink in *Notes* from the Leyden Museum for July, the form given to the nose in mounted specimens and figures of the proboscis-monkey of Borneo is quite incorrect. Instead of being sharply pointed, compressed, and projecting straight forwards, this appendage is expanded and depressed at the extremity, which hangs down in front of the upper jaw so as to conceal the greater part of the mouth in a full-face view.

MARINE fish-destroyers form the subject of an article by Prof. W. C. McIntosh in the May number of *Harper's Magazine*, in the course of which the chief types of extinct and living marine monsters destructive to sea-fish are described and illustrated. The author considers that such destroyers have done much more harm than man to food-fishes, and suggests that little good is done by regulations for controlling sea-fisheries.

Whether he is justified in classing the freshwater labyrinthodonts as marine fish-destroyers may be open to question; and his statement that the American Devonian fish Dinicthys occurs in the English "Old Red" does not appear to rest on good foundation. Why he should say that plesiosaurs "*continued* to the Mesozoic" is hard to understand; and his estimate of the size of the dinosaurian Atlantosaurus (100 feet long and 30 feet high) appears a gross exaggeration.

To the *Notes* from the Leyden Museum Dr. R. Horst contributes some remarks on the habits of the cocoanut-crab, based upon observations made on captive specimens at Batavia and living examples near Bantam by Mr. C. P. Sluiter. Recently some doubts have been expressed as to whether it is in the habit of ascending palm-trees. Mr. Sluiter has, however, seen these crabs climb to the top of mangrove-trees and palms fully 60 feet in height. What they did when at the top he was unable to ascertain, but, from observations made on captive specimens, he considers it probable that they were engaged in opening young cocoa-nuts and devouring their contents. Whether they have the power of opening ripe cocoanuts could not be determined, the specimens under observation merely fumbling such as were given them without attempting to penetrate the shell.

AT the conclusion of a memoir on the structure of the retina of the eye, published in the *Quarterly Journal of Microscopical Science* for July, Mr. H. M. Bernard states that this structure can no longer be regarded as being built up of a number of distinct cells, each of which possesses distinct and definite functions. On the contrary, if distinct cells ever exist, their walls must be broken down at a very early stage of development. In technical terms, the retina is a continuous cytoplasmic reticulum containing non-stationary embedded nuclei. The other papers in the same serial include one by Mr. H. J. Fleure on the relations of the kidneys in Haliotis, and a second, by Miss I. Drummond, on the development of Paludina.

IN most seismographs, the records are made on a sheet of glass or strip of paper which is either set in motion by an earthquake or has an ordinarily slow velocity increased at a somewhat advanced phase of the shock. In either case the interesting preliminary tremors are more or less completely lost. During the last three years, however, Dr. Cancani has avoided this loss by keeping the strip of paper continuously moving at the rate of six metres an hour. This velocity he has shown to be sufficient to decipher vibrations with a period of one-twentieth of a second and therefore above the lower limit of audibility. In a paper recently published (*Boll. Soc. Sismol. Ital.*, vol. vii. pp. 292–298), he maintains that even this velocity may be conveniently increased to one ten times as great and therefore capable, so far as speed is concerned, of registering the vibrations of earthquake-sounds occurring at the rate of 200 per second.

A WORTHY notice of the life and scientific work of the late Prof. P. G. Tait is contributed to the *Physical Review* (July) by Mr. A. Macfarlane, and is accompanied by a portrait of Tait printed in photogravure on plate paper.

MESSRS. CROSBY LOCKWOOD AND SON have ready for publication a volume entitled "Aërial Navigation," by Mr. Frederick Walker, dealing with the construction of dirigible balloons and other flying-machines; and another on the "Elements of Agricultural Geology," by Mr. P. McConnell.

IN the abstract of the paper on refractive indices by Mr. J. W. Gifford, published in NATURE of July 17 (p. 287), line 12 reads, "The difference of the angles of the prisms from 60° were in each case *less than* 4 *seconds of arc*." Mr. Gifford nforms us he should have said, "*less than* 4 *minutes of arc*."

AN interesting essay on "Clouds and Weather Signs," by Commander D. Wilson-Barker, has been reprinted from *Knowledge* and issued as an illustrated brochure. The pictures of clouds which the publication contains are exceptionally fine, and the descriptions of them should be the means of increasing the number of scientific observers of cloud phenomena.

IN the article on "Some New Forms of Geodetical Instruments" which appeared in last week's NATURE, it should have been mentioned that the illustrations of the instruments were from Sir Howard Grubb's paper in the *Transactions* of the Royal Dublin Society (vol. vii. No. 15). We are indebted to the Society for the use of the illustrations.

THE firm of Gustav Fischer, Jena, has begun the publication, in parts, of a new edition of the attractive work on deep-sea exploration entitled "Aus den Tiefen des Weltmeeres," by Prof. C. Chun. Although the original volume was remarkable for the large number of interesting and beautiful pictures, the second edition will contain many new illustrations. The work is one of five which are used as the text for an interesting essay on the methods and results of deep-sea investigations, in the current number of the *Quarterly Review*.

AN excellent series of lecture experiments illustrating different types of catalytic reactions is described by Messrs. Noyes and Sammet in vol. xli. of the *Zeitschrift für physikalische Chemie* (pp. 11–27). For convenience, catalysators are divided into seven classes, namely, carriers, absorbent contact-substances, electrolytic contact-substances, water, dissolved electrolytes, enzymes and inorganic colloid substances, and by means of the simple experiments described, the catalytic function of substances belonging to any one of these classes in increasing the velocity of chemical change can be demonstrated to an audience in a very satisfactory manner.

AN investigation of the rate of hydrolysis of sulphonic acid esters, published by R. Wegscheider in vol. xli. of the *Zeitschrift für physikalische Chemie*, has shown that this phenomenon is very different in character from that observed with the ordinary carboxylic esters. Whilst the latter are hydrolysed much more rapidly by solutions of acids than by pure water, the hydrogen ion of the acids being supposed to act as a catalytic agent, the hydrolysis of sulphonic acid esters is scarcely accelerated at all by acids. A further study of this subject would no doubt afford valuable information with regard to the essential difference between these two classes of acids.

To the numerous syntheses effected by means of the magnesium alkyl halogen compounds is to be added an extremely elegant method of passing up the series of carboxylic acids. Messrs. Houben and Kesselkaul, in the current number of the *Berichte*, describe the synthesis of carboxylic acids by means of the action of carbon dioxide upon these magnesium compounds. Thus, as an example, ethyl bromide is treated with magnesium in the usual way and a slow stream of carbon dioxide passed in; propionic acid is easily isolated from the product in a yield corresponding to 50 per cent. of the theoretical. Acetic, propionic, benzoic and phenylacetic acids have been synthesised in this way, so that the generality of the method is well established.

AT the Municipal Observatory of Montsouris the quantitative examination of atmospheric air has been carried out for a period of twenty-five years. About six years ago some special researches were commenced, under the direction of M. Albert Lévy, by MM. Henriet and Pécoul, the first results of which were presented to the Academy of Sciences in 1898. The fact was announced that atmospheric air which had been perfectly freed from carbon dioxide by an exhaustive treatment with potash and

baryta, on circulating repeatedly by means of a mercury circulator through a fresh quantity of baryta, gave appreciable amounts of barium carbonate corresponding to the production of amounts of carbon dioxide of an order nearly approaching, in some cases, the amount of carbon dioxide originally in the air. These facts were so extraordinary that the Academy appointed a commission, consisting of MM. Armand Gautier, Haller and Ad. Carnot, to repeat and report on this work. Their report is published in the current number of the *Comptes rendus*, and they confirm in every particular the views originally stated by MM. Henriet and Pécoul. M. Henriet also publishes in the same number an account of an attempt made to determine the nature of the gaseous substance present in the air capable of giving these results, and comes to the conclusion that there is present in the air of Paris the vapour of a substituted formamide, the slow hydrolysis of which by the baryta furnishes the carbon dioxide originally found.

THE additions to the Zoological Society's Gardens during the past week include a Black Lemur (*Lemur macaco*) from Madagascar, presented by Mr. Thomas Watson; a Hybrid Zebra (between *Equus burchelli* and *E. caballus*) from South Africa, presented by H.M. The King; a Caracal (*Felis caracal*) from South Africa, presented by Regimental Quatermaster-Sergeant Glenton, L.R.; two Javan Peafowls (*Pavo spicifer*) from Burmah, presented by Mr. O. F. Wheeler Cuffe; a —— Ouzel (*Merula*, sp. inc.) from India, presented by Miss Porter; thirteen Slow-worms (*Anguis fragilis*) British, presented by Mr. C. J. Frielander; a Mongoz Lemur (*Lemur mongoz*) from Madagascar, seven Cunningham's Skinks (*Egernia cunninghami*) from Australia, four Amphiumas (*Amphiuma means*), a Corn Snake (*Coluber guttatus*) from North America, two Ruddy Sheldrakes (*Tadorna casarca*) European, deposited; a Wapiti Deer (*Cervus canadensis*, ♂) from North America, purchased.

OUR ASTRONOMICAL COLUMN.

BRIGHT METEOR OF JULY 13.—Several letters referring to observations of the bright meteor of July 13 have been received, in addition to those mentioned last week (p. 281).

Mr. O. J. R. Howarth observed the meteor at Chelsea, his attention being attracted by a flash resembling a very powerful searchlight, of a bluish hue, which lit up the sky and street brightly for an instant. "On turning to discover the cause a trail of light of considerable breadth (perhaps 1°) was observed. It was of serpentine form, about 10° in length, of a granulated appearance, and gradually faded from a bright golden colour, remaining visible from eight to ten seconds. Its elevation was estimated at 60°, and its direction was about S.E. from Chelsea."

Mr. W. Gilles, observing at Deal, says:—"The meteor became visible about 10° S. of the zenith and left a luminous trail of a remarkably sinuous character at its commencement, which was visible for about one minute afterwards."

RADIAL VELOCITY OF THE ORION NEBULA.—In No. 5, vol. xv. of the *Astrophysical Journal*, Prof. H. C. Vogel gives an interesting description of the methods employed, and the results obtained, by Dr. Eberhard and himself in determining the radial velocity of the Orion nebula.

The spectrograms were obtained by Dr. Eberhard with a photographic refractor of the Potsdam Observatory, which has an aperture of 32·5 cm. and a focal length of 343 cm. Owing to the lens not being fully corrected it was impossible to photograph lines of greater wave-length than $H\gamma$. An exposure of 180 minutes, using a three-prism spectrograph, gave a spectrum in which, at $H\gamma$, 0·25 mm. corresponds to a difference of 0·424 $\mu\mu$, whilst an electrical heating apparatus enables the observer to maintain a constant temperature in the prism box within a tenth of a degree for several hours.

Seven spectrograms, taken between November 22, 1901, and February 22, 1902, each showing two iron comparison spectra in addition to the nebula spectrum, gave very uniform results, the mean of which, as measured by both observers, indicates a velocity of recession, relative to the sun, of $17·4 \pm 1$ km., and this agrees very well with the $17·7 \pm 1·28$ km. obtained by Keeler as the velocity of this object in his classical researches on the velocities of nebulæ.

Several drawings of the $H\gamma$ line which are given plainly indicate the existence of differential velocities in various parts of the nebula.

MOTION OF THE POLE.—In No. 523 of the *Astronomical Journal*, Dr. J. C. Chandler directs attention to the apparent existence of a fifteen months' periodical motion of the pole, which has not yet been identified. This apparent motion is so minute (0"·05) that Dr. Chandler hesitates to assert its real existence, but at the same time he cannot account for the constant differences in the coordinates by any other supposition, and he summarises his article with the following statement:—"In dealing with a phenomenon so obviously complex as these motions of the earth's axis are, and until we are certain of the superior limit of precision in astronomical measurement, it would be unphilosophical to ignore without examination such indications as these."

PHOTOGRAPHS OF THE PERSEIDS IN 1901.—M. J. Sykora communicates to the current number of the *Memorie della Societa degli Spettroscopisti Italiani* the results obtained by the staff of the Jouriew Observatory (Dorpat) in photographing the Perseid trails in August, 1901.

Seven meteor trails were found on the negatives obtained, but of these two were evidently not due to Perseids. Of the remaining five, two were remarkable, inasmuch as they show the explosion of meteors, one in the middle of its trail, the other at the end of its trail; drawings of these accompany the article.

Measurements of the trails in regard to the coordinates obtained from stellar images on the same negatives give the radiant point for August 11 as

$$\alpha = 43° \ 55'·8 \quad \delta = 57° \ 10'·3,$$

whilst the radiant point for August 12 is evidently slightly east of this position.

VARIABLE STARS.—2815 *U Geminorum*.—Mr. J. A. Parkhurst has observed the latest maximum of 2815 U Geminorum with the 12-inch and 40-inch refractors of the Yerkes Observatory, and finds a range of 3·04 magnitudes between April 3 and May 8, the maximum (9·76 m.) being attained at 13·9 h. on April 14.

Mr. Paul A. Yendell, of Dorchester, U.S.A., has made observations of the four following variable stars:—

2279 *T Monocerotis*.—Eleven observations of this star in 1900, and forty-six from December 1, 1901, to April 24, 1902, show four minima and five maxima.

2335 *W Geminorum*.—Fifty-one observations extending from November 24, 1901, to April 28, 1902, indicate five maxima and one minimum.

2509 *ζ Geminorum*.—Four maxima and three minima are deduced from thirty-two observations of this star made between December 27, 1901, and May 2, 1902.

2676 *U Monocerotis*.—Twenty observations from January 13 to April 14, 1902, include a minimum of 7·1 m. on January 30 and a maximum of 6·2 m. on February 12. (*Astronomical Journal*, No. 523).

THE AUGUST METEORIC SHOWER.

LIKE the great majority of meteoric streams, the Perseids return every year, and if they do not compose a really brilliant display they form a very noteworthy shower. An observer attentively watching the firmament on about August 11 may sometimes count 100 meteors in an hour, but the moon must be absent and the atmosphere very clear. In those years when it is most conspicuously exhibited it well repays observation even by those persons who do not specially apply themselves to this department of astronomy. At the close of July and opening of August there are comparatively few Perseids visible, but there is a rich shower of Aquarids at that particular epoch, so that meteors are generally pretty numerous, and occasionally surprisingly so.

Watching for these objects on ordinary nights is sometimes apt to prove tedious even to enthusiasts, but the Perseids are always sufficiently frequent and brilliant on about August 10, 11 and 12 to attract the interested attention of the most casual

stargazers. There are few more alluring spectacles than that afforded by the prolific fall of meteors on a genial August night, and we need not wonder that in the past few years observers of these phenomena have greatly increased, and that a more general interest than formerly is taken in recording apparitions of shooting stars.

This year the conditions will be favourable, for the moon will not offer any serious impediment to observation between about July 28 and August 12. It will be possible, therefore, to watch the progress of the shower through the fortnight comprising its more active stages. The weather is often a great drawback to investigations of this character (and this particularly applies to the English climate), for cloudy skies destroy the continuity of the work and occasion breaks which materially affect the value of the results. In watching a display similar to that of the Perseid stream, which is presented over a comparatively lengthy period, it is most essential to secure observations on many successive nights, so that the relative strength of the shower and the position of its radiant point may be determined at short and regular intervals. This is, however, not often practicable in England, though in exceptional cases there is little to take exception to in regard to prevalent weather. For instance, in August, 1901, thirteen of the fifteen nights from the 10th to 24th inclusive were clear, or partly so, and enabled observations to be obtained.

Everyone who views a meteoric shower would do well to record some of its leading features. One of the most important requirements is that the apparent paths of the meteors amongst the stars be registered. The fainter class of objects may be disregarded, but the lines of flight of the brighter meteors should be marked upon a celestial globe or star chart, and the right ascension and declination of the beginning and end points read off and entered into a book suitably ruled for the purpose. Such records, if carefully and accurately acquired, possess considerable value, as they furnish the materials from which the real paths and radiants of the individual meteors may be ascertained. Even those observers who have had no previous experience in work of this kind should make an effort to record the Perseid shower, for it will furnish an entertaining and instructive employment, and probably intensify their interest in the subject. In spite of the oft-repeated observation of the August display in past years, we have by no means completed our knowledge of its visible behaviour, and it should be further watched for data to enable us to more fully comprehend its various observational and theoretical aspects.

W. F. DENNING.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

IT is announced from Berlin that the Academy of Münster has been raised to the *status* of a University.

AT University College, London, on July 14, Mr. H. E. H. Smedley gave a demonstration of his methods of wax-modelling as applied to plant structures, more particularly with a view to elucidating complex anatomical relations.

AT Bedford College for Women (University of London), Dr. W. H. Willcox has been appointed lecturer in hygiene. The Pfeiffer scholarship in science has been awarded to Miss E. A. Bridger. Six open Pfeiffer scholarships of the value of 15 guineas will be awarded to the best candidates holding a degree, or equivalent, in arts or science wishing to train as secondary teachers. Application should be made to Miss H. Robertson, the head of the training department, not later than December 13, 1902.

AMONG the examiners for the London Matriculation Examinations of September, 1902, and June, 1903, we notice the following:—Mathematics, Mr. W. D. Eggar and Prof. G. B. Mathews, F.R.S.; physics, Dr. A. H. Fison and Mr. D. Rintoul, M.A.; chemistry, Mr. H. B. Baker, F.R.S., and Dr. G. S. Turpin; botany, Mr. H. Richardson and Mr. V. H. Blackman; zoology, Dr. G. Herbert Fowler and Mr. O. Latter; geography, Mr. G. G. Chisholm and Prof. W. W. Watts; geometrical and mechanical drawing, Mr. Walter Hewson and Mr. H. G. Christ.

IT will be remembered that in January last the Drapers' Company offered to devote the sum of 30,000*l.* to the extinction of the debt on University College, "provided that the Senate of the University of London and the Corporation of University College can, before February 28, 1903, agree upon a scheme for the incorporation of the college in the University, and such scheme be approved by the Company." The *University Gazette* of July 19 announces that the Senate has considered the proposal in all its bearings, both administrative and financial, and has approved the outlines of a scheme which had been drafted in conference with the council of the college as a preliminary step towards its realisation. Further negotiations are in progress between the University and the college with respect to certain details, and it is hoped that by the date specified a complete scheme for the incorporation of the college in the University may be agreed upon by both parties. The realisation of the scheme will depend upon whether it is possible to raise the necessary funds.

THE Directory of the Board of Education, South Kensington, has been superseded by "Supplementary Regulations for Secondary Day Schools and for Evening Schools," a copy of which has just been received. The greater part of the volume (pp. 42 to 241) consists of syllabuses of the subjects in which the Board of Education holds examinations. There are, in addition, syllabuses of certain subjects in which the Board does not hold examinations and lists of apparatus suitable for use in science classes. Some of the syllabuses contain very helpful instructions for experiments and other practical work. For instance, the syllabus of practical plane and solid geometry gives outlines and hints for a course of construction and measurement of an original character, much in advance of the traditional plane and solid geometry and geometrical drawing. The syllabuses which were formerly given in the Code for Evening Continuation Schools are now included in the volume before us, among the subjects being general rudimentary science and elementary rural science.

SCIENTIFIC SERIALS.

THE *Journal of Botany* for July opens with an account by Mr. G. S. West of algæ obtained from hot springs. One collection from Iceland consisted mainly of filamentous Myxophyceæ and small Diatoms. A new species of the genus Aulosira was found in considerable abundance, also *Mastigocladus laminosus*, which is commonly found in all hot springs. Twelve genera of green and blue-green algæ are represented. A second collection from Sira Ramau in the Malay Peninsula produced two new species, a Symploca and a Phormidium. Figures of the more important species are given on an accompanying plate.—Mr. Spencer le Moore describes five new species of Rubiaceæ, and three belonging to the Asclepiadaceæ, occurring in Dr. Rand's Rhodesian collections which are incorporated in the National Herbarium.—In the list of Glamorganshire plants observed by the Rev. E. S. Marshall and W. A. Shoolbred in June last year, several new records are given.—The varieties of *Hieracium anglicum* form the subject of a note by Mr. F. A Williams.—Mr. E. F. Linton contributes an appreciative biography of the late Mr. J. C. Mansel-Pleydell.

American Journal of Science, July.—On spectra arising from the dissociation of water vapour, and the presence of dark lines in these spectra, by John Trowbridge. With powerful discharges in hydrogen, oxygen and rarefied air the same spectrum is obtained, and this is regarded as arising from the dissociation of rarefied water vapour. From a study of the spectrum of powerful spark discharges under water the author concludes that dissociation of water vapour takes place in the atmosphere of the sun; oxygen must therefore be present. The dissociation of water vapour, under the effect of powerful electrical discharges in the presence of small amounts of atmospheric air, results in the production of argon, even in tubes presumably filled with dry hydrogen. The great brilliancy of the dissociation spectrum of water vapour, which obscures the spectra of metallic vapours, and the presence of dark lines due to photochemical reversals, show the need of caution in accepting photographic evidence in regard to the states of development of stars.—The occurrence of Greenockite on calcite from Joplin, Missouri, by H. B. Cornwall. The Greenockite occurs as a bright yellow, dust-like coating on the calcite, which can be easily rubbed off with the finger. Beneath this coating is a thin layer of sphalerite.—A quantitative study of variation in the fossil brachiopod *Platystrophia lnyx*, by E. R. Cumings and A. V. Mauck.—Studies of Eocene Mammalia in the Marsh

collection, Peabody Museum, by J. L. Wortman. The present instalment contains details of *Sinopa minor*, *Sinopa major*, together with observations upon the marsupial or metatherian relationships of the Creodonts. A summary of the results obtained for the whole series of Eocene Carnivora in the Marsh collection is appended.—New exposures of eruptive dikes in Syracuse, by P. L. Schneider.—Petrography of recently discovered dikes in Syracuse, N.Y., with note on the presence of melelite in the Green Street dike, by C. H. Smyth, jun.—The significance of certain Cretaceous outliers in the Klamath region, California, by O. H. Hershey.—The action of copper sulphate upon iron meteorites, by O. C. Farrington.—The classification of meteorites as active and passive towards solutions of copper sulphate, as given by Wöhler, is shown to be untenable. The rapidity with which the copper is deposited upon a thoroughly cleaned surface appears to decrease with the increase of the percentage of nickel, the temperature remaining constant, and hence meteoric iron, which always contains nickel, may be readily distinguished from terrestrial iron by this reagent.—A petrographical contribution to the geology of the eastern townships of the province of Quebec, by J. A. Dresser.—The action of carbon dioxide upon the borates of barium, by L. C. Jones. A criticism of the method for estimating boric acid of Morse and Burton.—Studies in the Cyperaceæ, by T. Holm.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 19.—"On the Correlation between the Barometric Height at Stations on the Eastern Side of the Atlantic." By Miss F. E. Cave-Brown-Cave, Research Student of Girton College, Cambridge, with some assistance from Karl Pearson, F.R.S., University College, London.

In a memoir on the correlation and variation of the barometric height at divers stations in the British Isles by Prof. Karl Pearson and Dr. Alice Lee, it is suggested (i.) that interesting results might be obtained by correlating the barometer at stations on the east and west sides of the Atlantic, allowing an interval of time between the observations (see *Phil. Trans.* vol. cxc. A, p. 459); and (ii.) that with a certain distance between stations, the correlation would be found to be negative, *i.e.* a high barometer at the one station corresponding to a low barometer at the second (see p. 467).

In order to deal with these points, steps were taken in 1897 to collect the necessary material. Twenty years, 1879–1898 inclusive, were selected for consideration, and the early morning barometric observations for these years, copied from material provided by the kindness of the British and other Meteorological Offices.

A preliminary study has been made of the East Atlantic stations, and this has impressed us with the desirability of continuing, if possible, our chain of stations right down the west coast of Africa, even to the Cape. The great mass of material to be dealt with, and the many new problems which arise in an almost entirely novel investigation of this kind, have meant, of course, very slow progress, and while publication of the final conclusions must be delayed for some time yet, it seems desirable to draw attention to a few of the results already reached for the East Atlantic stations.

In the first place it was soon discovered that the winter and summer months (equinox to equinox) must be treated separately. It was already known that the average height varied considerably in the summer and winter months, but there are also very significant differences in the variability, and, in what we are most concerned with, the *correlation*. For example, there is hardly any correlation (0·04) between Lisbon and Valencia in the summer, but in the winter it is quite considerable (0·22). Further, the results worked out in two groups of ten years each, show that very sensible differences in mean, variation, and correlation can exist between one decade and the next, so that at least twenty and probably more years are desirable if we are to obtain steady values for the barometric constants. In the next place, while we have found a small but sensible cross Atlantic barometric correlation after a definite interval of time, we must wait for more complete American data, and for still closer investigation of the best interval for different stations before results on this point are published. The second suggestion, however, has been amply verified, and to draw attention to this is the principal object of the present preliminary notice.

As we go generally south from any station, we reach a point at which for readings on the same day there is no correlation at all. *For stations beyond this point the correlation becomes negative, reaches a negative maximum, and then begins to decrease.* Clearly it must reach a second zero. What happens after this? Does the correlation remain zero for all greater distances? To fully answer this problem we must obtain data south of Sierra Leone—in fact, we want data for St. Helena, Ascension, and the Cape, and have taken steps to obtain them.

Thus Valencia is positively correlated with Bødø. Lisbon, however, is negatively correlated with Bødø, but positively with Valencia. We require to go as far south as Funchal to find a negative correlation with Valencia. To get a negative correlation with Lisbon we must go as far as Sierra Leone, which has become positive again for both Bødø and Valencia. At St. Helena we have our second negative correlation zone for both Bødø and Valencia, while we are only in the second positive zone for Lisbon. In other words, the curve of barometric correlation with distance from a station appears to give roughly the form:—

We do not find with increasing distance a diminishing correlation, as of a curve rapidly asymptoting to $o\,x$, but as it were a wave-curve of diminishing amplitude. There is not apparently an area of positive correlation surrounded by a field of zero correlation, but going south there are only *points* of zero correlation, not *regions* of zero correlation. Probably if the area of investigation can be extended we shall find *lines* not zones of zero correlation round each station, separating districts of positive and negative correlation. What we are certain about is, that a zone of positive correlation is followed by a zone of negative correlation. What we are less sure about is, that this negative zone is again followed by a positive zone of much less intensity, but our rather meagre results certainly suggest it.

Full numerical data are given in the paper for Bødø, Skudesnes, Valencia, Lisbon and Funchal, and less complete data for Sierra Leone and St. Helena.

We hope shortly to complete our calculations to the Cape, and then to finish the work already begun on the American stations. Meanwhile, we think that the correlation of a series of stations following roughly a parallel of latitude across Europe and Russian Asia would throw a flood of light on whether a chain of roughly north and south stations differs wholly in character from a chain of east and west stations. The magnitude of the computations, however, almost precludes the idea that any individual worker or workers can hope to complete such a task within a reasonable period.

DUBLIN.

Royal Dublin Society, June 18.—The Right Rev. Monsignor Molloy in the chair.—Prof. J. Joly, F.R.S., communicated a paper by Mr. W. B. Wright, of the Geological Survey, on some results of glacial drainage round Montpelier Hill, co. Dublin. At the lowest point of the ridge which connects the outstanding hill of Montpelier with the main mass of the Dublin Mountains to the south is a dry, transverse gap, connecting the valleys on either side; this gap cuts directly across the junction of the granite and slate, and has apparently no reference to the structure of the rock in which it is excavated. The occurrence in one of the side valleys of a thick deposit of gravels, ending in a fairly straight line on the Boulder Clay plain, which stretches up to its mouth, is suggestive of the occurrence in this valley, during the later stages of the decay of the ice sheet, of an ice-dammed lake which had its overflow channel through the gap. The gravel is composed for the most part of limestone and other material foreign to the ice sheet, indicating that the depositing waters flowed mainly from the ice sheet. At the other end of the gap are some mounds of granite and slaty material, probably the débris from it. At a subsequent period the drainage appears

to have been directed round the north side of Montpelier Hill, and has left its traces here in a series of terraces and incipient channels.—Dr. E. J. McWeeney made some remarks on a bacteriological method of air examination.—Mr. H. J. Seymour, of the Geological Survey, gave a short note on the occurrence of cassiterite in the Tertiary granite of the Mourne Mountains, co. Down.—Monsignor Molloy described and demonstrated working models of a three phase generator and a three-phase motor, suitable for lecture purposes.

PARIS.

Academy of Sciences, July 15.—M. Bouquet de la Grye in the chair.—On the structure and history of the lunar crust: observations suggested by the fifth and sixth numbers of the "Photographic Atlas of the Moon," published by the University of Paris, by MM. Lœwy and P. Puiseux.—Preparation and properties of a silicide of vanadium, by MM. H. Moissan and Holt. A mixture of vanadium oxide, V_2O_3, with about five times its weight of pure silicon is heated in the electric furnace for four or five minutes. The compound VSi_2 is formed; it can also be prepared by the action of magnesium powder upon a mixture of silicon and vanadic acid. Heated in a current of hydrochloric acid gives silicochloroform and a mixture of chlorides of vanadium.—On the coccidia found in the kidney of *Rana esculenta* and on the general infection which it produces, by MM. A. Laveran and F. Mesnil. It is shown that this organism, *Hyaloklossia Lieberkühni* of Labbé, is really an Isospora, and is renamed by the author *Isospora Lieberkühni*. Diagrams are given showing its different stages of growth; it causes an acute mixed nephritis in the frog.—The direct hydrogenation of acetylenic hydrocarbons by the method of contact, by MM. Paul Sabatier and J. B. Senderens. The method of direct hydrogenation by contact with nickel or copper has been applied to œnanthylidene and phenyl-acetylene. With nickel the chief product in the first case is normal heptane; with copper a heptene together with a small amount of heptane. With phenyl-acetylene nickel gives chiefly ethylcyclohexane; with copper ethylbenzene, with small quantities of diphenyl-butane and metastyrolene.—Report on the experiments made at the Observatory of Montsouris relating to the composition of atmospheric air, by MM. Armand Gautier, Haller and Ad. Carnot. The experiments of MM. Lévy, Henriet and Pécoul on the existence of an easily oxidisable gaseous compound in the air of Paris have been repeated and confirmed (see p. 308).—The use of hail rockets, by M. E. Vidal. Evidences are given of the power possessed by the rockets of breaking up storm clouds, and especially of preventing damage to vines by hail.—Application of the method of the arithmetical mean to the surfaces of Riemann, by M. A. Korn.—On the formation of liquid drops and the law of Tate, by MM. Leduc and Sacerdote. The law of Tate states that the weight of the drops of a given liquid falling from the extremity of a tube is proportional to the radius of the end of this tube. It is shown that this is only approximately true and that the usual reasoning establishing this law is inexact. A new expression is deduced which is submitted to an experimental study.—On binary accords, by M. A. Guillemin.—On a new organic vapour in atmospheric air, by M. H. Henriet. Filtered air is mixed with steam and this is then condensed. The condensed water was then examined and found to contain a minute amount of what would appear to be a substituted formamide.—On the properties and constitution of the peroxides of zinc, by M. de Forcrand.—On oxyisopropylphosphinic acid, by M. C. Marie.—On a new method of preparation of α-substituted β-ketonic esters, by M. René Locquin.—The electric resistivities of pathological blood serums and serous effusions in man, by MM. Lesage and Dongier.—The zymase from *Eurotiopsis Gayoni*, by M. Mazé. It has been found that the zymase is present in considerable quantity in the developing mycelium, but that with aërobic cultures the quantity of the zymase present in unit weight of mycelium diminishes rapidly with the age of the cultures.—On the cure of "la casse" in wines by the addition of sulphurous acid, by M. J. Laborde. The author criticises the views of MM. Bouffard and Dienert, and gives fresh experimental evidence in favour of the hypothesis originally advanced by him.—Researches on the Culicides of Algeria, by M. H. Soulié.—On the treatment of black rot, by M. A. Prunet. Mildew and black rot being different diseases the same remedies should not be applied to both. The maximum interval which should be allowed to elapse between two successive treatments with the copper sulphate solution has been determined experimentally.—On the lower Gothlandian of the Armorican *massif*, by M. F. Kerforne.—Some facts, new or little known, concerning the Glacial period, by M. David Martin.

NEW SOUTH WALES.

Linnean Society, May 28.—Mr. J. H. Maiden, president, in the chair.—Descriptions of new genera and species of Lepidoptera (Fam. Noctuidæ), by Dr. A. Jefferis Turner.—An ascobacterium from the sugar cane, by Mr. R. Greig Smith.—Preliminary note on the geology of the Queensland coast, with references to the geography of the Queensland and New South Wales plateau, by Mr. E. C. Andrews. An attempt is here made to refer the origin of the present coastal configuration of Queensland and Northern New South Wales primarily to a recent variable crustal movement. The topography of the Cordillera and the continental shelf is found to throw light on Barrier Reef problems.—Notes on the botany of the interior of New South Wales (part vi.), by Mr. R. H. Cambage. The conspicuous botany of the country between Marsden, near Lake Cowal, and Narrandera is described. Mention is made of the damage done to certain trees, notably dogwood (*Myoporum deserti*), by the rabbits.

CONTENTS.

THURSDAY, JULY 31, 1902.

AUTOMOBILES.

Schule des automobil Fahrers. By Wolfgang Vogel. Pp. viii + 189. (Berlin: Schmidt, 1902.) Price m. 2·60.

MR. WOLFGANG VOGEL has moved about on his motor cars with such pleasure to himself that it has resulted in a desire to share that pleasure with others, and he addresses his book chiefly to those who are unlearned, not only in motor cars, but even in the rudiments of the usage of machines. He is right in this, for they are numerous.

Probably the largest percentage of persons who are quite ignorant of mechanical matters exists among the upper classes. The millions who work in factories, delve in mines, and direct some one or other of the innumerable agricultural appliances have had an acquaintance with machinery forced upon them. Few of these would require a diagram and many words to indicate the use of a sight feed oiler or a Stauffer lubricator, by whatever name they might distinguish them.

But among those who can buy motor cars these things are still a mystery, and it is likely that the automobile movement will cause a very important alteration in the mental attitude of the so-called cultivated classes towards machines, and thence towards mathematics and science. At present, therefore, it is reasonable that a book such as Herr Vogel's should give elementary diagrams of the Otto cycle and obvious sketches of the much-sketched induction coil.

Chapter ii. shows how explosive gas is made by spray or vapour from the liquid petrol mixed with air, how it is controlled in amount, ignited electrically, and voided noiselessly after it is burnt.

A very justifiable preference is shown for the secondary over the primary battery and for the dynamo over either for the purpose of making sparks to fire the charge; but it is remarkable how much less perfect is the electrical part of automobiles than might have been expected. Instead of working fervently in this new field, the electrician has evidently settled down to making money in his other dearly earned preserves.

If we compare the amount of energy utilised in igniting the charge in an explosion engine with the bulk and weight of the usual ignition equipment we shall feel some surprise. If we further consider how easy it is to make an electrical instrument "fool proof," especially when it is devoid of moving parts, we shall be astonished at the numbers of electrical breakdowns—the loose wires, oily contacts, broken terminals, which characterise every beginner's early motor-car runs.

It has been noted in various automobile competitions that electrical troubles were prominent in cars entered by manufacturers and agents, and almost absent from cars entered and owned by private persons, the differences being ascribed to the superior electrical knowledge of most of the amateurs who had sufficient mechanical tendencies to tempt them to what then was, in its early days, an odious sport.

There still remains much to be done to diminish the high cost, high weight, large bulk and frequent opportunities of breakdown which characterise even the most modern motor cars, but these questions of design and improvement do not exercise our author, who contents himself with instructions how to use cars as they are.

It may be mentioned that the book contains many tabulated forms, which give, in order, the necessary operations for getting the machine ready before running, for starting up, and in case of breakdown. Copies of these tables should be of great value to the beginner, and he is intended to use them until thoroughly familiar with his machine.

The "self-mover" which is more likely than any other to create a stir in the world, and which, until he is educated up to it, the pedestrian and carriage person hates, the motorist despises, and the ordinary cyclist is jealous of, is the motor bicycle. This most useful machine by no means receives its proper share of attention at the hands of our author, who ascribes to it only two pages. It will be avenged on him some day, even if it be only in the matter of the sale of his book.

In chapter iii., Herr Wolfgang Vogel divides automobiles into cycles, voiturettes and motor cars, without showing any very good reason for so doing, though he incidentally points out that the driving of a motor tricycle will probably come more easily to one who has never been accustomed to ride a bicycle. In chapter iv. he deals with brakes, and explains simply and clearly the necessity for differential gear which so often puzzles the tyro. The subsequent chapters are given over to trailers and the like. Possible breakdowns and their remedies are dealt with.

Part ii. begins by dealing with minor accessories and the repairs of pneumatic tubes. Hints are given for lengthened tours, and a table is appended which includes all the hundred and one articles which are so apt to be left behind. The reader may gather several wrinkles from this chapter; they all deserve the description of "praktisch."

Chapters iii. and iv., which are devoted to the description of tours from Berlin to the Rhine, Switzerland and Italy, made by the author, are lightly and interestingly written, and give the reader an excellent idea of the pleasures and difficulties incidental to such tours. The run over the Stilfser Joch, the highest bit of road in Europe, seems likely to provide as much excitement as modern man could desire.

The necessity for being provided with enough money of the various countries passed through and an ample number of spare parts is pointed out, with illustrations from the author's own experience of delays at an exacting Customs Office. A knowledge of languages is, of course, desirable.

The author proffers an admirable suggestion that continental automobile clubs should compile a register of the hotels which have suitable "stabling" for motor cars, and not confine their attention to the places where petrol can be procured. He is, of course, not cognisant of the good work done by the English Automobile Club both in this and in every other direction for road and route improvement.

The author favours petrol cars, and, according to him, the purchase of a motor cycle only engenders the

P

desire for a voiturette, which had better have been satisfied from the first. If he were to sit on one or two committees of the English club above named, he would learn to his astonishment that a number of members who already possess a luxurious car are adding a motor cycle to their "stable," a fact which is hardly in accord with his opinion.

From the brevity of part iii., which deals with electromotors, and of part iv., which devotes to steam cars the short space of four pages, he would appear to be less than kind to the formidable competitors of his favourite petrol explosion engine.

On the whole, the book gives in a very simple and interesting manner a large amount of information which must prove invaluable to the beginner, and may with advantage be studied even by those who are more conversant with the vagaries of the motor car.

. The author's style is unusually understandable to English readers, and with a little judicious "skipping" the sense can easily be followed, owing to the number and clearness of the illustrations, without the laborious necessity of using a dictionary.

MERVYN O'GORMAN.

COMPARATIVE ANATOMY OF ANIMALS.

An Introduction to the Study of the Comparative Anatomy of Animals. Vol. ii. By G. C. Bourne, M.A., D.Sc. Pp. xv + 321. (London: G. Bell and Sons, 1902.) Price 4*s*. 6*d*.

DR. BOURNE'S work is divided into thirteen chapters, which, though serial with those of the preceding volume, are separately paged. In addition, there is a short "conclusions" chapter—in reality a concise summary of the contents of the book, with some good advice to the student—and also an excellent index.

The text treats of the cœlomate Metazoa, with a special leaning to the developmental side, which the author regards as indispensable to "a just appreciation of the problems of comparative anatomy." Of the thirteen chapters, the first is restricted to the Platyhelmia, with especial reference to the liver fluke; the second and third to the earthworm alone; the fifth mainly to the mussel; the sixth to the snail; the eighth to the crayfish; the ninth to the cockroach; and the eleventh to the dogfish. The two concluding chapters are devoted respectively to the development of the frog and a very general survey of the field of mammalian morphology; while the three which remain are in turn given to the Annelida, Crustacea, and Cephalochorda in general, to Apus and Amphioxus in particular.

In the selection of material, the author has been guided by the requirements of the "preliminary and intermediate science examinations in the universities of Great Britain." By way of illustration he gives us seventy-seven text figures, many of which are new and meritorious. The researches of Benham, von Boutin, Ehlers, Fraipoint, Hatschek, Kowalevsky, Lacaze-Duthiers, Reichenbach, Vejdovsky, Wilson, and others, have been duly laid to account, with acknowledgment, such as might well have been similarly accorded to certain English workers upon whose labours the author has drawn. Of the author's own diagrams, those illustrating the development of the mammal may be cited as excellent; but even here clearness might well have been further ensured, had the alimentary canal been delineated in outline, as giving rise to the allantois and yolk-sac.

The book is fully up to date and well worthy its predecessor and its author's reputation, and one of its chief attractions is its literary style. Such criticism as we offer must needs be detailed. For example, in defining the urinogenital organs of the mammal, the uterus masculinus is regarded as the persistent lower end of the Müllerian duct, with an accompanying illustration which most nearly recalls the condition in the rabbit. It might have been advantageous to point out that in this animal the organ generally thus named has been proved, by von Kölliker, Pallin, and others, to be a product of fusion of the vesiculæ seminales, and no uterus masculinus at all. Similarly, a little more precision might well have been given to both description and figure of the crayfish nervous system, by directing attention to the approximation of ganglia about the sternal artery, which this genus so instructively exhibits, as a determining feature of the decapod type. With the crayfish, again, the statement that the "gastrolith" "is supposed to form a reserve of calcareous matter to supply material for the new armour formed after ecdysis" is most certainly erroneous, and mention might rather have been made of the evidence for its association with this very function. Nor is the author more fortunate in his treatment of the decapod mandible, the wholly endopoditic nature of the "palp" of which cannot be maintained in knowledge of the facts recorded by Boas. And when we come to questions of doubt, we cannot accept the declaration of the supposed composite nature of the "cerebral ganglion-pair" in Anodon, deduced, as it would seem to be, by analogy from Pelseneer's statements for Nucula.

As to terminology, while the author is at most points sound, we consider him in error in the term "demibranch" as defining the gills of sharks; *hemi*branch it should surely be, since the root noun is Greek. Again, we much prefer the term *thoracic* to dorsal, as applied to the mid-trunk vertebræ of the mammal; and while we consider the description of the mammalian coracoid inadequate, we can only refer to the statement that the corpus callosum is characteristic of the mammalian brain as misleading, since the Eutheria alone possess it as now defined, viz. as a tract of neopallial commissural fibres invading the alveus.

The foregoing amounts almost to hypercriticism, where all else is so well done; and we would rather congratulate the author on the production of a book which, while professedly written up to the requirements of an examination system, is thoroughly trustworthy and eminently readable and instructive. It fully realises our expectations, expressed on reviewing its companion volume (NATURE, vol. lxii. p. 364); and, as an additional recommendation, it may be said that, in order to ensure clearness and continuity, details are in places suppressed, reference being given to authoritative sources whence they may be found already described.

There is an interesting erratum of a page and a quarter which calls for special comment, viz. a corrected figure and description of the synangium of the frog,

which, as now described, is in line with previous knowledge and most recent investigation. The figure in the first volume which it is to replace, incomprehensible as it stands, is now admitted by the author to have been due to confusion, in the attempt to reconstruct his own rough drawings during the intervals of military duty. If only for this we forgive him, despite his somewhat emphatic contentment with the original, now condemned. An attractive elegance is a leading feature of this book, and by this it is calculated to draw the reader to its subject. In this respect it contrasts both forcibly and favourably with the baldness of expression and lack of culture which characterise many of its would-be competitors.

THE CLASSICS OF PHYSICAL SCIENCE.

Scientific Memoirs. Edited by J. S. Ames, Ph.D. Fifteen volumes, prices varying from .60 to 1.00 dollar. each. (New York: American Book Company, 1898 to 1902.)

IT is refreshing to meet with this series. Not that the contents are novel, though recent things are not lacking. It is the aim of the series which is stimulating. Our students are gradually being degraded into a reliance upon text-books for nourishment instead of being brought up on a study of scientific classics. It was not ever thus. Time was when text-books were almost unknown, and knowledge of science had to be acquired by a study of original sources. The more modern craze for, and reliance upon, examinational tests has altered all that. Nowadays a man must know a little bit of every branch of the rapidly extending circle of sciences in order to take a county scholarship or a degree. And text-books spring up by the dozen to supply the very special wants of any newly created examination. It is possible, and it is to be hoped, that the new regulations in the University of London will tend to remedy this state of affairs. Much greater stress is to be laid upon a knowledge of recently published work, and the habit of mind that is so induced is bound to be a healthy one. We wish, too, that for the less recent work men were more encouraged to put text-books on one side and study some one branch at least in the original memoirs.

This handy series in fifteen volumes is a move in the right direction. It consists of translations or reprints (in English) of memoirs dating from the rise of physical science to the present day. Each volume is confined to one subject, has a separate editor, who writes a very short preface—in part historical, in part elucidatory—and also a brief biographical sketch of each of the writers whose memoirs are selected from. The first volume consists of papers by Gay-Lussac, Joule, and Wm. Thomson and Joule on the "Free Expansion of Gases." In the brief introductory sketch it might have been well if the editor had pointed out the essential distinction between the earlier and the later experiments. Thus, while the absence of a fall of temperature in Gay-Lussac's experiments is so far a proof of Mayer's hypothesis, its absence in Joule and Thomson's experiments would not have proved it. In fact, the editor is labouring under a very common mistake in thinking that the experiments all satisfy the condition of zero performance of external work; this is the case in the first but not in the last. It is a pity that the expression "free expansion" is not reserved for cases which satisfy the above condition, and some other term (*e.g.* throttle expansion—the term of the refrigerating engineer) be employed where the conditions are those which obtain in porous plug experiments or the "wire drawing" of steam.

The other volumes are as follows:—

Vol. ii. "Prismatic and Diffraction Spectra." Papers by Fraunhofer and Wollaston.

Vol. iii. "Röntgen Rays." The now historical papers of Röntgen and Stokes (the Wilde Lecture) and J. J. Thomson.

Vol. iv. "The Modern Theory of Solutions." Pfeffer, van 't Hoff, Arrhenius and Raoult.

Vol. v. "The Laws of Gases." Robert Boyle and Amagat.

Vol. vi. "The Second Law of Thermodynamics.' Carnot, Clausius and Thomson.

Vol. vii. "The Fundamental Laws of Electrolytic Conduction." Faraday, Hittorf and Kohlrausch.

Vol. viii. "The Effects of a Magnetic Field on Radiation." Faraday, Kerr and Zeeman.

Is it a fact, as stated by the editor, that in the Hall effect "the stream lines of an electric current flowing through a thin conducting sheet transverse to a magnetic field are deflected"? That the lines of electric force are deflected is, of course, certain; but the two statements are not equivalent.

Vol. ix. "'The Laws of Gravitation." Newton, Bouguer, Cavendish, with abstracts from others.

Vol. x. "The Wave Theory of Light." Huygens, Young and Fresnel.

Vols. xi. and xii. "The Discovery of Induced Electric Currents." Joseph Henry and Faraday.

Vol. xiii. "The Foundations of Stereo-chemistry." Pasteur, van 't Hoff, Le Bel and Wislicenus.

Vol. xiv. "The Expansion of Gases by Heat." Dalton, Gay-Lussac, Regnault and Chappuis.

Vol. xv. "The Laws of Radiation and Absorption." Prévost, Stewart, Kirchhoff, and Kirchhoff and Bunsen.

The editor attributes to Kirchhoff the first rigorous proofs of the celebrated law connecting emission and absorption. This is the common view; but in the light of Rayleigh's recent vindication of Stewart in the *Philosophical Magazine* this attribution is inadmissible.

It will be seen from the above very brief summary what the kind of selection has been. Other editors might very well have selected differently without effecting any improvement.

If a criticism may be attempted, it is that objection may be easily raised to the abridgment which several of the papers have undergone. Much may, of course, be urged in favour of this pruning when carefully done; but the necessity for it is certainly to be regretted. It recalls the similar process which novels have been obliged to submit to—a process which suggested to *Punch* the brilliant idea of republishing pictures with parts deleted The editors carefully point out, however, when they have applied the knife, and they appear to have used it with care.

At the end of each volume is a bibliography, in which reference to allied papers is made.

With this our task is done. This is not the time to discuss the matter of the papers themselves. Let it only

be said that they are all classics, and we ask the student to decide in favour of reading them in preference to some brief text-book summary. He will find no great mathematical difficulty in any of them which would make it impossible for him to understand them thoroughly without being otherwise helped.

PURE AND APPLIED BACTERIOLOGY.

Traité de Bactériologie pure et appliquée à la Médicine et à l'Hygiène. Par MM. P. Miquel et R. Cambier. Pp. xv + 1059. (Paris: C. Naud, 1902.) Price fr. 45.

THIS work, comprising more than one thousand pages and a comprehensive index, is a valuable addition to the already extensive literature of the subject of bacteriology. As the title of the work indicates, it deals with bacteriology, not only from the purely scientific point of view, but also from the technical and applied, inasmuch as its application to industry and to sanitation forms an important part of the work. The book is divided into four principal divisions. The first division treats of the morphology, the chemical, physical and other conditions concerning the composition, growth and reproduction of bacteria, and capable of affecting them favourably or unfavourably. It deals, further, with the methods used in cultivation, the culture media, their preparation and their physiological action in the human and animal body. In the same division is found an account of the methods of staining bacteria, their spores and cilia, both from cultures and from animal tissues. And lastly, the optical instruments used in the study of bacteria (microscopes, photomicrographs, magnifying glasses, &c.) are treated in chapter ix.

All these subjects are treated in a clear and comprehensive manner, very useful and sufficient for the student of bacteriology, and in many instances brought up to the most recent times, so that both student and original worker have the advantage of the most recent improvements in the methods of the study of bacteria. While, therefore, the reader has in the 236 pages constituting this first part all that it is of real importance to know concerning the most modern methods in bacteriology, he misses a good deal concerning some modern views of the morphology and classification (Migula, Meyer).

The second part, comprising in five chapters about 325 pages, is the one which for the student of medicine and hygiene is the most important, since it describes the different species of pathogenic bacteria of diseases of man and animals.

This part of the book will be found less satisfactory than the first, because in our opinion it is in several respects somewhat imperfect; the descriptions of the different species, their characters and actions might be more detailed; it is deficient in the theories of immunity, and notably in regard to suitable and representative illustrations. The absence of proper and accurate illustrations, not only in this, but in other portions of the book, seems inexplicable. The authors devote time and trouble to teaching photomicrography, yet there is not in the whole book a single photomicrograph to illustrate a single species of the many hundreds described. We have no fault to find with the use of schematic drawings, such as occur in this book, when it is a question merely to illustrate general characters as to the aspect and morphology of the bacteria, but we fail to understand the value of such illustrations as occur in this second portion of the work ("Pathogenic Bacteria"), where, in total disregard of all natural conditions, a few tinted dots or a few tinted lines are here produced to represent cocci or bacilli. Another subject in this section seems to us deserving of explanation. It is this. All text-books, all writers and all those who have contributed to their discovery have recognised and described as "bacilli" the various species that cause "hæmorrhagic septicæmia" in different animals, yet here in this book we are suddenly brought to a full stop, and for no adequate reason, by having all these different bacilli (fowl cholera, swine plague, swine fever, wildseuche, duck cholera, grouse disease, &c.) grouped amongst "Micrococques Pathogènes."

The third and fourth portions of the work (pp. 568–888 and 888–1038 respectively) in our opinion are excellent, both as regards treatment and arrangement, and denote the hand of the master, and considering the known works and reputation of M. Miquel, this is quite what was to be expected. The third part deals with the important processes of fermentations caused by bacteria, as lactic, acetic, butyric, pectic, &c.; with the production of pigment; with the bacteria of air, water and soil; with putrefaction; with the bacteria occurring in the different parts of human and animal bodies, and with phosphorescent bacteria.

The fourth and last part deals with the principal methods of analysis of air, water and soil as practised and applied by the authors and others in their own systematic work; further, with the purification of potable waters; and last, but not least, with the most efficient means of disinfection.

As stated already, these two sections of the book form, by their clear and concise descriptions and by their complete treatment, an advance over all existing books, and we venture to say that the book on this account alone deserves to be, and will doubtless become, of universal use.

There is one further merit in this book not to be taken lightly, and that is the copious references to the original works of other authors, notably French and German. There are references also to English and American workers, but, as is usual with most German and French writers, to which we in England have become by this time well accustomed, references to English and American literature occur rather sparingly and are treated in a somewhat stepmotherly fashion.

E. KLEIN.

OUR BOOK SHELF.

General Investigations of Curved Surfaces of 1827 and 1825. By Karl Friedrich Gauss. Translated with Notes and a Bibliography by James Caddall Morehead, A.M., M.S., and Adam Miller Hiltebeitel, A.M. Pp. viii + 127. (Princeton, N.J., U.S.A.: The Princeton Library Publishing Association, 1902.) Price 1·75 dollars.

THIS is an English translation of the classic memoirs of Gauss on the theory of surfaces. The first paper is that which was presented to the Royal Society of Göttingen in

1827, and is still regarded as the most finished and useful introduction to the study of infinitesimal geometry. The translation is based on a copy of the original paper, but in the work of preparing it and the present notes all the other editions were consulted. This is followed by a translation of the abstract presented by Gauss to the Royal Society of Göttingen. Under the title of "*New* General Investigations of Curved Surfaces," the translators next give a paper really written by Gauss at an earlier date (1825), but which was not published until the eighth volume of Gauss's works appeared in 1900. Both papers contain the fundamental properties of what is now known as Gauss's measure of curvature, the theorem that the spherical excess of a geodesic polygon is proportional to the corresponding area on the auxiliary sphere, and the proof that the locus of points the geodesic distances of which from a fixed point are equal cuts these geodesics orthogonally. The paper of 1825, however, contains introductory matter on curvature in a plane which was omitted by Gauss from his 1827 paper, and while, in 1825, Gauss used geodesic polar coordinates only, in 1827 he introduced the notion of generalised coordinates p and q. It will thus be seen that the order in which the papers have been printed is the reverse of chronological order.

A large number of notes have been inserted by the translators, those on the 1827 paper occupying twenty-eight pages. Many of these notes contain proofs of results merely stated by Gauss; others consist of explanatory matter, restatements of Gauss's conclusions, or simple corollaries. The "bibliography" contains a list of 343 papers dealing chiefly with the following subjects:—Curvilinear coordinates, geodesic and isometric lines, curvature of surfaces, deformation of surfaces, orthogonal systems and the general theory of surfaces. A large proportion of the papers listed are of comparatively recent date, thus affording a guide to the literature about curved surfaces which has grown up in the development of methods first laid down by Gauss.

The Elements of Mind. By H. J. Brooks. Pp. xviii + 312. (London: Longmans, Green and Co., 1902.) Price 10*s.* 6*d.* net.

THE author claims to have made the correlation of chemistry physiology and psychology possible by the discovery of the "simple elementary substances of mind" which, according to him, "when compounded with those of force and matter, constitute the mysterious substance we call life." It is not easy to gather his exact meaning, as his definitions of his fundamental terms are partly defective, partly circular. Matter and force he leaves undefined; of life he simply says that he "uses it in its ordinary sense." Mind—when not further defined by a restricting adjective—is "everything that is not matter," a definition which would include, *e.g.*, space, time and the series of natural logarithms. As an instance of a definition which is circular as well as obscure, "By Ego I mean that which is known as the personality of the brain. . . . Personality I employ in the ordinary sense of a person's physical and mental characteristics." Substance, again, should have been defined with special accuracy by a writer who attaches so much importance to his professed discovery of the "elementary substances" of mind. Yet all that Mr. Brooks has to say of it is that "substance is philosophically described as that which exists and remains." Now space and time may be said to "exist and remain"; are they substances or are they not? Mr. Brooks, of course, knows whether he means to say that they are, but a reader is nonplussed. And finally, what exactly does Mr. Brooks mean by an "element"? By "elements of matter," as his examples show, he means chemically undecomposable constituent parts; but what exactly are meant by the "elements" of force, which "scientists with somewhat less success have described"? So far as the absence of precise definition permits us to form a judgment, Mr. Brooks's doctrine seems to agree with the "mind-stuff" theory of W. K. Clifford. He quotes Prof. James's trenchant refutation of this theory of the composition of a unitary consciousness out of atomic constituents and attempts to turn its edge. He does not, however, seem to realise its full force. The case of "light" is no exception to James's contention that "all the combinations which we know are effects wrought by the units said to be combined" upon something other than themselves. Still less is the relation between an organism and its members the same as that between an aggregate and its parts. I confess that I have been unable to discover in Mr. Brooks's book any one consistent theory of the relation between his elements and the single whole which he calls the "greater Ego." Sometimes this whole is spoken of as controlling, dominating and using the elements, sometimes as built up by their mechanical interaction. So with his general metaphysical theory. He appears sometimes to hold that "mind," "force" and "matter" are things which can compound quasi-chemically, sometimes that they are different "aspects" of a single reality. Where I do understand him, he appears to be expounding in novel language a psychology of the extreme associationist type, though not without moments of deeper insight in which he seems to uphold the ultimate identity of mind and body. A. E. T.

A Graduated Collection of Problems in Electricity. By Prof. Robert Weber, D.Sc. Translated from the third French edition by E. A. O'Keeffe, B.E., M.I.E.E. Pp. xv + 351. (London: E. and F. N. Spon, Ltd.; New York: Spon and Chamberlain, 1902.) Price 7*s.* 6*d.* net.

THIS book is intended to be a help to the teacher of physics, and consists of a collection of problems of varying difficulty in almost all the branches of electrical work. The third edition differs chiefly from the previous ones in the inclusion of some fresh problems and in the careful revision and correction of errors which has been made. The author has adopted the plan of giving the solution immediately after each problem, and though objections may be urged against this method, we think on the whole it is the most satisfactory for a book of this kind. Those interested in electricity from its practical side will regret that most of the problems are of an academic character. Thus, to quote one example, the section on glow lamps gives the impression that lamps are usually made for 40 or 50 volts and that lighting is carried out by means of primary batteries. Occasionally one comes across a problem in which the data are not sufficient in reality. Apart from a few minor defects of this sort, the book is a very useful one, as the questions are well calculated to show whether or not the student has really grasped the meaning of the work he is doing, which should be the principal aim of a teacher. The addition of a short section on units and a number of tables enhances the value of the work. M. S.

Junior Chemistry and Physics. By W. Jerome Harrison. Pp. vi + 224. (London: Blackie and Son, Ltd, 1902.) Price 1*s.* 6*d.*

SOME of the fundamental principles of physics and chemistry are simply described in this book. Common objects are used as subjects of observation and experiment, and an attempt is made to show the scientific aspects of familiar things. The first few pages seem out of place in a book of this character. Pupils beginning the study of science ought not to be troubled with such statements as "The universe is composed of matter," "We have given the name of *ether* to an extremely rare kind of matter," "Matter has extension," "Matter is indestructible," &c. These subjects belong to the later stages of natural philosophy.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Penetrating Rays from Radio-active Substances.

THE permanent radio-active substances uranium, thorium and radium all give out two types of rays, one easily absorbed and non-deviable by a magnetic field and the other more penetrating in character and deviated by a magnetic field. In addition to these rays, Villard, using the photographic method, first drew attention to the existence of some very penetrating rays from radium non-deviable by a magnetic field. This result was confirmed by Becquerel.

I have recently examined all these radio-active substances by the electrical method, and have found that thorium, and also the excited radio-activity produced by thorium and radium, emit some rays as penetrating in character as those from radium. Uranium, in comparison with thorium and radium, emits little, if any, of this radiation.

These rays are extraordinarily penetrating in character, and pass readily through great thicknesses of matter. They are certainly as penetrating as the most penetrating rays given out by a hard X-ray tube. The amount of ionisation produced by them is only a very small fraction of that produced by the other two types of radiation. Using testing vessels of ordinary size, the ionisation due to the penetrating rays is of the order of 1 part in 100 of that due to the deviable rays and 1 part in 10,000 of that due to the easily absorbed rays.

In the experiments on radium, 0·7 gram of radium chloride, of activity 1000 times that of uranium, was used. The radiation from this, after its passage through 1 cm. of lead, caused a rapid movement of the needle in the sensitive electrometer employed. The radium was placed in a thick-walled lead vessel and a piece of aluminium waxed tightly over the top to prevent the escape of the emanation. The following numbers illustrate the diminution of the rate of leak in a testing vessel, placed above the radium, with the thickness of the lead traversed by the radiation :—

Thickness of lead.	Current.
·72 cm.	1
·72 + ·62 cm.	·60
,, + 1·24 ,,	·37
,, + 1·86 ,,	·25
,, + 2·50 ,,	·16

The current with ·72 cm. of lead over the radium is taken as unity. It will thus be seen that the current falls off approximately in a geometrical progression with the thickness traversed, and that after passing through 1·86 cm. of lead the intensity is reduced to about one-quarter.

The following table shows the thickness of different metals traversed before the intensity is reduced to one-half :—

Metal.	Thickness in cm.
Mercury	·75
Lead	·9
Tin	1·8
Copper	2·2
Zinc	2·5
Iron	2·5

Assuming this law of absorption to hold, the rays would pass through a thickness of about 7 cm. of lead, 19 cm. of iron and about 150 cm. of water before the intensity would be reduced by absorption to one per cent. of its original value.

The amount of the penetrating radiation from thorium is about the same as for radium, taking into account the ratio of their radio-activities. As the radium employed was about 1000 times as active as thorium, it was necessary to work with a kilogram of thorium nitrate to obtain about the same amount of rays as from the ·7 gr. of radium.

Experiments were also made to see if the excited radio-activity, due to thorium and radium, which gives out deviable and non-deviable rays, also emits these penetrating rays. In order to get measurable effects, it was necessary to obtain intense excited activity. For this purpose a zinc plate was exposed as kathode in a closed vessel containing 300 gr. of thoria. A lead wire was also made very active by exposure as kathode for six hours in a vessel containing a large amount of radium emanation, obtained by bubbling air through a solution of radium chloride. The excited radiation from these two sources was found to include rays about as penetrating in character as those from radium and thorium. The intensity of these rays diminished with the time, rapidly for radium and more slowly for thorium excited radiation. This diminution with time is probably directly connected with the rate of decay of the other known types of radiation from excited bodies.

Since the penetrating rays are present in thorium and radium, and also in the excited radiations due to these bodies, and are absent in uranium, it seems probable that the penetrating rays in both radium and thorium are due to the excited radio-activity, produced in the mass of the compound by the emanations which are unable to escape into the air. According to this view, the production of penetrating rays is a function of that portion of radio-active matter which causes excited radio-activity.

Connection between Absorption and Density.—Some experiments were made to see how the absorption of the rays by matter varied with the density. The coefficient of absorption λ was determined by noting the ratio of the intensities of the rays after passing through a known thickness of matter. The following table illustrates the results :—

Substance.	Penetrating rays.		Deviable rays from uranium.	
	λ	$\frac{\lambda}{\text{density}}$	λ	$\frac{\lambda}{\text{density}}$
Water	·033	·033	—	—
Glass	·086	·035	14·0	5·7
Iron	·28	·036	44	5·6
Zinc	·28	·039	—	—

A comparison table on the right is added for the deviable rays given out by uranium. It will be seen that the quotient of absorption by density is in neither case a constant, but the differences are no greater for the non-deviable penetrating rays than for the deviable rays of uranium. It is interesting to observe that the value of λ divided by the density is for both types of rays twice as great for lead as for glass or iron. It will be seen from the above table that the penetrating rays from radium, compared with the deviable rays of uranium, pass through a thickness of glass about 160 times greater for the same reduction of intensity.

Comparison of penetrating Rays with Röntgen and Kathode Rays.—The question at once arises as to whether these very penetrating rays are projected particles like kathode rays or a type of Röntgen rays. The fact that the penetrating rays are not deviable by a magnetic field seems, at first sight, to show that they cannot be kathode rays. I have repeated the experiments of Villard, and have been unable to obtain any appreciable deviation of the rays, which had passed through ·6 cm. of lead, even in a very strong magnetic field. The photographic method was used, and four days' exposure of the plate was necessary to get an appreciable impression. In some other respects, however, the rays seem more closely allied to kathode than to Röntgen rays. It is well known that Röntgen rays produce much greater ionisation in gases like sulphuretted hydrogen and hydrochloric acid gas than in air, although the differences in density are not large. For example, sulphuretted hydrogen gives six times and hydrochloric acid gas nine times the conductivity of air. On the other hand, with kathode rays the conductivity observed is only slightly greater than for air.

The experiment was made of filling the testing vessel with sulphuretted hydrogen, when it was found that the current for the penetrating rays from radium was only slightly greater than for air. Both this experiment and the results for the variation of absorption of the rays with the density of matter seem to show that the penetrating rays have a closer resemblance to kathode than to Röntgen rays.

It must, however, be remembered that the observations on the relative conductivity of gases and the relative absorption of

metals for Röntgen rays have only been determined for rays far less penetrating in character than these rays from thorium and radium. Benoist has shown that the relative absorption of Röntgen rays by matter depends to a large extent on the kind of rays employed. "Hard" rays give quite different ratios from "soft" rays. For penetrating Röntgen rays the absorption of the rays by a *given weight* of the elements is a continuous and increasing function of their atomic weights. From the curve of absorption, given in his paper, the variations of absorption with density are much greater for Röntgen rays than for the penetrating rays from radio-active substances.

A very important question arises in discussing the character of these penetrating rays. According to the electromagnetic theory, developed by J. J. Thomson and Heaviside, the apparent mass of an electron increases with the speed, and when the velocity of the electron is equal to the velocity of light its apparent mass is infinite. An electron moving with the velocity of light would be unaffected by a magnetic field.

It does not seem at all improbable that some of the electrons from thorium and radium are travelling with a velocity very nearly equal to that of light, for Kaufmann has recently determined the velocity of the most penetrating deviable rays from radium and found it to be about 95 per cent. of the velocity of light.

The power of these rapidly moving electrons of penetrating through solid matter increases very rapidly with the speed. From general theoretical considerations of the rapid increase of mass with speed, it is to be expected that the penetrating power would increase very rapidly as the speed of light was approached. Now we have already shown that these penetrating rays have very similar properties, as regards absorption and ionisation, to rapidly moving electrons. In addition, they possess the properties of great penetrative power and of non-deviation by a magnetic field, which, according to theory, belong to electrons moving with a velocity very nearly equal to that of light. It is thus possible that these rays are made up of electrons projected with a speed of about 186,000 miles per second.

An interesting speculation arises from the experimental observation that the excited radiations from bodies include these very penetrating rays. Elster and Geitel have recently shown that excited radio-activity can be produced from the atmosphere by exposing a negatively charged wire in the open air. This excited activity is very similar in properties to that produced by thorium and radium. Since the earth is negative with regard to the upper atmosphere, the surface of the earth is itself made radioactive. From the nature of the phenomenon, it necessarily follows that, not only the surface of the earth, but also the whole interior surface of buildings is covered with an invisible deposit of radioactive matter. From the close similarity in the nature of this excited activity from the air with that from radio-active bodies, it is not improbable that the excited radiations from the air include also some of the penetrating rays. If this is the case, our bodies must be continually subject in a small degree to something very like the Röntgen ray treatment, which is now so popular in medical circles. It would also follow that the "spontaneous" ionisation of air, observed in closed vessels by Elster and Geitel and C. T. R. Wilson, may be due, in part at least, to the presence of these rays, which so readily pass through the walls of the containing vessels. E. RUTHERFORD.

McGill University, Montreal, July 6.

The Future of the Victoria University.

THE interesting contribution on the subject of the Victoria University which Prof. Schuster has made to your columns (July 19, p. 252) invites a few words of reply from one who does not regard the possible disruption of the University with the same complacency.

It may be unknown to many readers of NATURE that the proposals which would disband the University arose in such a way as to preclude that close and careful deliberation on the future of the University and its colleges which would have resulted in a peaceful maintenance of the *status quo* or in a harmonious process of separation. We should otherwise have been saved from the unfortunate situation in which the University is now placed, when one of the colleges and its county is left standing alone for the maintenance of the University.

I refer to this because it might be supposed that the existing state of affairs was the outcome of something like a quarrel. There has been no quarrel; the three colleges of the Victoria University have worked together with a degree of smoothness and good feeling that might seem hardly possible to those who know the strong local sentiment of the two counties and the three towns. There have indeed been many controverted questions in the University history, but the lines of party have, I think, been usually independent of the colleges.

The question of disruption having been raised in such a way that the University itself could not consider it by means of an unpledged tribunal, the Yorkshire College, believing the movement to be detrimental to the interests of education, desired that there should be a Government inquiry by means of a Royal Commission or other body of high authority. This proposal has not been accepted by the majority of the University Court, and as the matter rests now we have the application of Liverpool for a university formally opposed by Yorkshire and formally approved by Owens College, subject to Manchester being also allowed an independent university.

I have no wish to enter here upon the general question of the relative merits of single college and federal universities, but I think there is something to be said on another question of more immediate practical importance, and that is, whether an action so grave as the disestablishment of a university should not be the subject of a strict and impartial public inquiry.

It is true, no doubt, that the Privy Council may be trusted to give a careful and impartial consideration to the question before it, but in the ordinary course of things that would not involve a public inquiry, and the grounds on which any decision was reached would not be made known.

I believe that the future of the Victoria University is a question not affecting that University alone. It raises the much greater issue of the future of university organisation in England, and it seems to me to be of the first importance that the real grounds, if there are any, for the disruption of the federal Victoria University should be clearly set forth in evidence and endorsed by competent authority.

Prof. Schuster says that "the Victoria University is now practically an examining body, which unites all disadvantages." That is just the sort of statement I wish to see sifted by an impartial tribunal. Many of us would say that such a statement cannot be serious; it seems so exaggerated.

It is proposed to dissolve a great educational corporation which after twenty-three years of hard work has acquired real momentum and has come to be recognised as a factor in educational affairs not inconsiderable when compared even with the older universities. I am one of those who believe that a factor of this particular kind has been and is one of the most urgent needs of our time. I believe also that the defects of the Victoria University, which are undoubted, might be largely rectified by a less drastic process than disruption, and that with a revised constitution the University might continue to exist with greater freedom and ease for its constituent colleges and with undiminished effect in their collective action as an enlightened "modern" force on English education.

Surely at least the question is worthy of the most careful consideration and is one that calls for an open inquiry.

In conclusion, I deplore the haste which has been made by advocates of disruption to convince the public of the defects of a University which after all may be obliged to continue its existence. ARTHUR SMITHELLS.

July 14.

IN writing about the future of the Victoria University in a scientific journal I was anxious to avoid all questions which are immaterial to the main point. Prof. Smithells's letter deals mainly with side issues. The lines of cleavage at our board meetings interest no one but ourselves, and it does not matter now whether Liverpool might or might not have proceeded in a more academic manner.

The position at present is this:—The two senior colleges, representing about three-quarters of the University, believe that independent universities will in future be able to carry out their educational work better than the present federation. Prof. Smithells thinks that we ought to have accepted the proposal of the Yorkshire College to have the whole question referred to a Royal Commission. But surely the only course likely to be followed by men who know their own minds is to ask for what they want; at any rate, it is the only way to get it. It is fortunate, however, that Prof. Smithells's predilection in favour of a federal university may yet be satisfied. Yorkshire is quite large enough to supply the material for a federation, and as an

experimental philosopher he ought to rejoice at the possibility of having two rival systems put to the test in two neighbouring counties Prof. Smithells's reference to the momentum acquired by the Victoria University is not a happy one, as he ought to know that if a moving body separates under the action of internal forces, momentum is conserved, while kinetic energy is increased.

As regards the concluding sentence of his letter, it seems to me that while advocating public inquiry by Royal Commission he deplores public discussion before the only tribunal which is competent to deal with this question. It is to men who have had practical experience of university teaching, or who by helping to advance knowledge have acquired a right to speak with authority on the organisation of a teaching university, that I addressed myself in writing to you on the subject.

ARTHUR SCHUSTER.

Science and the London Matriculation Examination.

THE late June matriculation examination of the University of London being the last general examination for all candidates under the old regulations, it may be worth while to note one or two things revealed by it.

(1) Out of just under 3000 candidates, fifteen only gained a place in the honours division, but none of these were from what we should recognise (in the accepted parlance) as "public schools," and no female name appears in that division.

(2) The great public schools are represented only by Harrow, Westminster and Shrewsbury (with five names between them); and if we extend the connotation of the term "public school" to include such schools as the great day-schools of the metropolis, such semi-day-schools as Dulwich and Highgate and such public schools of the second rank as Felsted, Repton and Epsom, we can only (with a liberal interpretation of the term) accredit them with somewhat less than sixty names in the whole list. More exactly, the number one counts is fifty-seven, of whom *only four represent an "optional science,"* the remaining fifty-three having offered an "optional language."

These facts seem to represent a poor return for all the *talk* we have heard of late in connection with scientific education. The fair inferences from them seem to be, (1) that the teaching of languages is immensely stronger in this country than the teaching of science; (2) that the University of London as yet scarcely touches the education of the country as represented by the great public schools of England; (3) that, so far as the public schools generally are concerned, science is regarded still as a πάρεργον (with the exception of Epsom, and to a less extent the City of London School, St. Paul's School and Clifton College). In some cases, perhaps, it may be inefficiently taught, but in many more it is handicapped by the biassed autocracy of the classical headmaster. Gentlemen of that type even with the best intentions lack real sympathy; and the responsibility for the results (little short of disastrous) must ultimately rest with the governing bodies of the great schools of the country. While this condition of things remains, can we wonder at the dearth of brain-power exhibited by our officers as a body in the late war, or at that development of mere loquacity which so often characterises the utterances of our public men and puts the thinker entirely into the shade? One is inclined to ask the question whether present attempts at educational legislation are likely to prove other than abortive when our legislators for the most part need to be educated to a true appreciation of science, its nature, its aims and its methods.

A. IRVING.

Bishop's Stortford, July 21.

The Recent Fireball.

THE very brilliant meteor which made its appearance at about 10h. 30m. on Sunday night, July 13, is on record, so far as is known at present (July 26), as having been seen from 106 places. A large proportion of these are in the counties of Middlesex, Surrey, Kent and Essex, while isolated accounts come from as far away as Devon, Wales, Lancashire, Lincolnshire and Norfolk. Many reports of the phenomenon give no details whatever; very few give trustworthy data concerning its path in the heavens. The meteor was fortunately seen by Mr. Denning at Bristol, and from descriptions by him and a few other observers who carefully noted the position of the meteor its approximate real path in the air has been computed. At its first appearance the object seems to have been at an elevation of 86½ miles, the place of its final extinction being 52½ miles over the Straits of Dover. The course of 45 miles was over a line 11 miles to the west of one joining St. Omer and Cape Gris Nez. The fireball must have presented a splendid sight to the inhabitants of the district of France over which it passed, and it is greatly to be hoped that some descriptions will be available from there in order that the above result may be confirmed or corrected.

The radiant-point was probably at $316° + 30°$, which, though a well-known shower-centre in July, does not seem to have provided such a similarly brilliant member during recent years.

The features of the fireball may be gathered from an inspection of some of the descriptions. The brightness was at least as great as that of the moon, this great light being due to the bursting of the meteor, which then gradually faded. A serpentine streak was afterwards visible, fading away in turn. Some portions of this were traced by some observers for a few minutes afterwards. The duration of flight was variously estimated. If an average of two seconds be taken, as seems permissible, the speed would be 22½ miles per second.

WALTER E. BESLEY.

Sunspots and Wind.

THE Greenwich tables of wind-direction contain much, I think, that is suggestive of sunspot influence. Take, *e.g.*, the days of northerly wind in the first quarter of the year (according to the classification N., E., S., W.).

Curve A shows how their number has varied since 1841. In B, each year-point represents an average of five values (on an enlarged scale). D is a curve for the whole year, similarly obtained. C is the inverted sunspot curve.

(It should be stated that the values prior to 1860 eir a little by defect, owing to the manner of dealing with calms, in the earlier table used.)

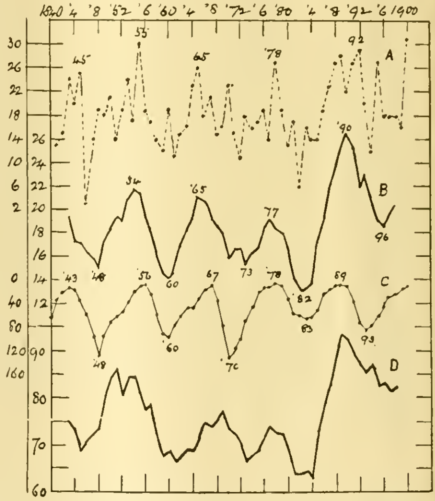

FIG. 1.—A. Days of northerly wind (Greenwich) in first quarter of year (actual variations). B. Result of smoothing A with averages of five. C. Inverted sunspot curve. D. Days of northerly wind (Greenwich) *in year*, smoothed.

Regarding curve B (especially), are we obliged to think that this consistent correspondence through sixty years, showing always less northerly wind about maxima than about the adjoining minima, is a matter of chance? If we are to accept the views given in a recent presidential address (from which, I think, there must be considerable dissent), that is how it is to be interpreted.

A systematic inquiry into the configuration of high-pressure systems in Europe about sunspot maxima and minima, especially in the winter half, would, I believe, be fruitful in results.

ALEX. B. MACDOWALL.

THE CHELSEA PHYSIC GARDEN.

MANY of the readers of NATURE will be aware that the Physic Garden at Chelsea has for some time past been undergoing numerous alterations and improvements in order to enable it once more to take up its old position as a centre of botanical instruction and research. New laboratories and plant-houses have been erected, and on Friday, July 25, these were opened by Earl Cadogan, K.G., who expressed the hope that a long career of usefulness now lay before them. Mr. Hayes-Fisher, M.P., who presided on the occasion of the ceremony and who has throughout the reorganisation taken a most active part in the matter, gave a sketch of the history of the Garden and an outline of the purposes to which it is henceforth to be devoted.

Since its foundation by the Society of Apothecaries some 220 years ago, the Physic Garden has passed through many vicissitudes of fame and fortune, and its history is full of interest to the antiquary and the botanist alike. It has numbered many eminent men amongst its past curators, and as Sir W. Thiselton-Dyer remarked, it gave a curator to that younger physic garden which has since developed into the magnificent institution at Kew. Although it was primarily designed to provide for the proper study of medicinal plants, it soon began to serve as a channel through which new foreign plants became introduced into this country, and it is said (though not without contradiction) that the first cedars of Lebanon to be grown in Britain were the four trees planted in 1683 and formerly thriving in the Garden, of which the last only finally succumbed some two or three years ago.

It seems to have excited some surprise even in those early years to discover how well plants were found to succeed in the Garden, and Evelyn, who visited it in 1685, remarks on the excellent condition of the collections as a whole, and he also incidentally refers to the then novel method of heating the conservatory by heat conveyed subterraneously from a stove situated under the building.

Some fifty years later, Linnæus in 1736 visited the Garden, and he records in his diary that Millar (the gardener) allowed him to collect a number of plants and also gave him some dried specimens. The note is of interest as illustrating the importance which at that time attached to the place. For many years it continued to be more or less used, chiefly by medical students, but its maintenance proved a heavy tax on the somewhat narrow resources of the Society of Apothecaries, and as neither the Royal Society nor the College of Physicians, both of which had an interest in it under the terms of the original conveyance, in accordance with the intentions and wishes of Sir Hans Sloane, would accept the responsibility, the Charity Commissioners were approached with the view of devising a scheme which would provide for the relinquishing of the trust whilst at the same time securing its continuance as a scientific institution. The late Sir Henry Longley became interested in the matter, and a departmental committee, consisting of Sir Henry Longley, Sir W. Thiselton-Dyer and Mr. Spring-Rice, was appointed by the Treasury to inquire into the matter.

The outcome of the various deliberations and negotiations has been the passing of a Scheme in 1899 whereby was ensured the preservation for the practical study of botany in London of a venerable institution and an excellent garden. The Trustees of the London Parochial Charities, subject to certain conditions, provide an annual income of 800*l.*, whilst the Treasury, through the Board of Education, subsidises it by a further amount of 150*l.* per annum in consideration of certain rights and privileges thereby attaching to the Royal College of Science. The Garden is administered by the Trustees of the London Parochial Charities, and by a Committee of Management, the seventeen members of which are appointed in accordance with definite regulations laid down in the scheme.

In adapting the Garden to its new purposes various necessary changes have been effected in connection both with the buildings and also with the outdoor department. A strip of land required for the purpose of widening Queen's Road was sold to the Chelsea Borough Council, and this involved the demolition of the old lecture-rooms and curator's house, together with two lean-to greenhouses. Moreover, the main range of plant-houses had fallen into a hopelessly ruinous condition, and their removal was decided upon, the intention being to erect a new range of plant-houses, together with laboratories and a curator's residence, along the revised north-western boundary of the Garden. This has now been done, and it was to witness the opening of these new buildings that the gathering assembled on Friday last.

The laboratories and curator's house have been designed by Mr. G. E. Rivers, of H.M. Office of Works. The laboratories are comprised in a two-storied building which contains on the ground floor a large main class-room, to be fitted up with working tables; out of this open a greenhouse, to be used for physiological purposes, and also two smaller rooms and a convenient dark-room. Upstairs there is a large laboratory which will also be available for lecture purposes, and there are three other smaller rooms, one of which will be appropriated to contain the library and working garden herbarium. The basement of the building has ample convenience for storing and other purposes.

The plant-houses, built by Messrs. Foster and Pearson, are arranged on the corridor system that experience shows to be both economical and easily worked. A single corridor runs along inside the boundary wall, and out of this open three houses designed for stove, intermediate and cool plants respectively. Two excellent pits are connected with the range and are heated by the same boilers. The houses, taken as a whole, are not large, but they will suffice for the practical requirements of the Garden.

Only one of the old glass-houses—a large lean-to on the south-western wall—has been retained. It is an unheated structure, and it was here that Moore, the well-known authority on ferns, grew the greater part of his collection. The rest of the old plant-houses have now, as has already been said, disappeared. The place where they formerly stood is marked by the three small tanks formerly built into them, but which are now situated in the grass in front of the laboratories.

Doubts have often been expressed as to whether it would be possible to grow the plants necessary to enable the Garden to discharge its new functions. A visit to the place would soon dispel any such fears, for it may be at once seen that a very large proportion of the herbaceous species flourish luxuriantly under cultivation there. The fine aspect, with the river frontage, is partly responsible for this, and it is fortunate that for educational uses the greater part of the needed specimens can be provided in the form of herbaceous species. Some of these are of course more difficult to manage than others, but experience shows that by the exercise of discretion in the selection of appropriate material the obstacles imposed by climate and environment in the way of forming a representative collection such as is needed by students can for the most part be easily surmounted.

In the Garden, as in the laboratories, it is intended that provision shall be made for experimental and other investigations, and certain plots of ground will be set aside for these purposes as occasion may arise. And in order that effect may be given to these intentions, general regulations under which the various resources of the Garden may be made as widely available as practicable will be issued early in the ensuing autumn.

A QUARTETTE OF MUSEUM PUBLICATIONS.[1]

BY the issue of the handsome and beautifully illustrated volume standing first on our list, the Trustees of the British Museum have followed the lead set a couple of years ago by the appearance of the "Monograph of Christmas Island," and have thus added a second work describing the fauna of a definite area to the long list of publications bearing their name on the title-page. And there can be little doubt that this new departure will be welcomed by naturalists and by the public at large. In the present instance it has afforded a means of commemorating in a graceful and fitting manner the munificence and generosity of the originator of the *Southern Cross* expedition, and has likewise furnished zoological science with a valuable memoir on the fauna, flora and petrology of the Antarctic. How valuable such a publication is at the present time needs no comment here; and it will accordingly suffice to say that with the "Antarctic Manual" and the present volume the scientific staff of the *Discovery* will, on their return, have an excellent basis for the commencement of their work.

FIG. 1.—Adelia Penguins on their Nests. (*By permission of Sir George Newnes, Bart.*)

The *Southern Cross* expedition, we may remind our readers, was fitted out in 1898 by Sir George Newnes, regardless of expense, the zoological staff consisting of Messrs. N. Hanson and H. Evans. On the return of the vessel, Sir G. Newnes, with characteristic generosity, presented the British Museum with the first "pick" of the natural history collections, desiring that the duplicates should be distributed among other museums, both British and foreign. Unhappily, Mr. Hanson did not survive to superintend the sorting and description of the extensive collections formed during the voyage, and there was consequently considerable difficulty in identifying some of the specimens, more especially in correlating the skulls with the skins of the fine series of Antarctic seals, which formed, perhaps, the gem of the entire collection. Moreover, the loss of an important memoir on the white seal which had been drawn up with great care by Mr. Hanson was an irretrievable misfortune.

The task of describing the different portions of the collection was divided among a large number of specialists, the editorship of the memoirs relating to vertebrates being assigned by the Director of the Natural History Branch of the Museum to Dr. Bowdler Sharpe, while Mr. F. J. Bell prepared for press the invertebrate section of the work. Altogether the work comprises twenty-two separate memoirs, for which the services of as many specialists were secured.

The new forms described in the volume are not very numerous. They include, however, three genera of fishes, each represented by one or more new species, and two specific representatives of a previously named genus. The other new forms are all invertebrates. In this connection it may be observed that there is a want of uniformity between the plans followed by the two editors. In the vertebrate section each new form is indicated as such in the heading, but this is not so in the invertebrate part. It is not a matter of much importance, but still uniformity would have been advisable.

The most generally interesting sections of the book are undoubtedly those treating of the seals and the penguins. The description of the seals was originally undertaken by Captain Barrett-Hamilton, who, we believe, had to leave for South Africa before the volume was finished. Owing to the destruction of the labels, this gentleman was unable to correlate the skins with the skulls, and it was consequently only the latter that could be specifically identified with certainty; his descriptions are, therefore, chiefly limited to the skull and dentition. At a later period it was, however, found possible to assign the skins to their respective species, and their description was undertaken by Mr. E. A. Wilson, now serving on board the *Discovery*. When this identification was made, that eminent artist Mr. H. Grönvold was commissioned to draw the five plates of seals, which were coloured by Mr. Wilson himself and form one of the most striking features of the book. The exclusively Antarctic seals are four in number, namely Weddell's seal (*Leptonychotes weddelli*), the leopard-seal (*Ogmorhinus leptonyx*), the white seal (*Lobodon carcinophagus*) and Ross's seal (*Ommatophoca rossi*), each the sole representative of its genus. Ross's seal, previously known only by the skull, is a most extraordinary-looking creature, recalling, in the curious inflation of the throat, a pouter-pigeon. Captain Barrett-Hamilton comments on the remarkable dissimilarity presented by the dentition of the four species and correlates this with the nature of their food. Specimens of three of the species are exhibited in the Natural History Museum.

The penguins, together with the other birds, are described by Dr. Bowdler Sharpe. They include three species, of which two, the emperor-penguin (*Aptenodytes forsteri*) and the Adelia penguin (*Pygoscelis adeliae*) receive the largest share of attention. Two coloured plates are devoted to the latter, while numerous text-figures (two of which we are enabled to reproduce) illustrate the haunts and habits of both species. The Adelia penguin is a migratory species, which congregates during

[1] (1) "Report on the Collections of Natural History made in the Antarctic Regions during the Voyage of the *Southern Cross*." Edited by R. B. Sharpe and F. J. Bell. Pp. ix + 344; illustrated.

the breeding season in enormous rookeries, and special interest attaches to a photograph of the arrival of a party of these birds on the Antarctic land. The curious discovery that these birds as they ascend the cliffs make deep groovings in the solid rocks with their claws was not announced in time to be mentioned in the volume. The eighth and last coloured plate represents the remarkable colour-phases presented by the eggs of MacCormick's skua (*Megalestris maccormicki*).

All concerned in this important contribution to natural history are to be congratulated on the successful completion of a by no means easy task.

Our congratulations must likewise be offered to the author of the second work on our list, the first volume of which has been already noticed in these columns. Since the appearance of the first volume the Museum collection of eggs has received a most important addition by the bequest of the Crowley collection, noted on account of its richness in the eggs of Australian birds. The registration of this vast collection was not completed when the MS. of a large portion of the second volume went to press, so that Mr. Oates has been compelled to add an appendix. The collection will also, we presume, render necessary an appendix to the first volume, if only to include the great auk's egg which forms one of its treasures. Previously the Museum possessed only two bleached eggs of that species, which are entered in the catalogue as valueless.

Even with the addition of the Crowley bequest, the Museum collection is by no means so extensive as is desirable, although it is probably far ahead of any other. To say nothing of many species totally unrepresented, there are many birds—among them such well-known forms as the secretary-bird, the bay vulture and the South African griffon vulture—of which there are not more than two or three eggs in the collection.

Among the special rarities recorded in the volume before us, mention may be made of two eggs of the sanderling (*Calidris arenaria*)—the one from Grinnell-land and the other from Iceland—and three assigned to the knot (*Tringa canutus*). Two of these latter (belonging to the Crowley bequest) were taken in Iceland, while the third is one of a clutch of four, said to have been taken with the hen-bird, sent to the late Mr. H. Seebohm from Disco Island. All three specimens are alike; but, according to Mr. Oates, "they bear an exact resemblance in size, shape and colour to some of the eggs of the common snipe. The genuineness of these eggs therefore requires confirmation, but they are probably correctly identified." Here we may call attention to what, in our opinion, is an imperfection in the indexing of the volume. Species of which there is a supplemental notice in the appendix are duly recorded in the index, but this is not the case with genera. It is true that such genera do not receive a separate heading in the appendix, but we nevertheless think they should have been indexed as occurring there; it would have made reference easier.

Other rarities catalogued include eggs of the American noble snipe (*Gallinago nobilis*), two; the Malagasy snipe (*G. macrodactyla*), three; the black jacana (*Jacana nigra*), two; the black-winged courser (*Rhinopterus chalcopterus*), three; the African wattled crane (*Bugeranus carunculatus*), three; the white-winged trumpeter (*Psophia carinata*), two; and the seriema (*Cariama cristata*), three. Of the two species last mentioned, all the eggs in the collection were laid in confinement, those of the trumpeter in Mr. Blaauw's aviary in Holland and those of the seriema in the London Zoological Society's menagerie.

The volume is illustrated by fourteen beautifully coloured plates of eggs, drawn and coloured by Mr. H. Grönvold. Apart from their special interest to oologists, these figures are of great value to the general naturalist as giving him a much better idea of the prevalent type of coloration characterising the eggs of different groups of birds than can be obtained from the figures of exclusively British species. Both author and editor appear to have executed their tasks carefully and conscientiously, and when the remaining volumes are issued the work will not only be invaluable, but absolutely unique.

The works standing third and fourth in our list are of a totally different type from those already noticed, and are intended for the general public rather than for scientific naturalists, although even the latter class of readers may perhaps gain some information from them in regard to those sections of zoology of which they have not made a special study. Before proceeding further we may say a word with regard to the covers and title-pages of these two little works. In the "Mammal Guide" the words "British Museum" are printed in large type and "Department of Zoology" in smaller type, whereas just the reverse of this occurs in the "Coral Guide." Apart from the question of uniformity (which we consider by no means an unimportant one), there seems no doubt that the former style is far the most preferable. It may be added that the address "Cromwell Road, London, S.W.," which appears on the cover of the "Coral Guide" is, in our opinion, quite unnecessary, and not suitable to the dignity and importance of a great public institution.

FIG. 2.—Adelia Penguins Paired. (*By permission of Sir George Newnes Bart.*)

If, however, it is required in the one "Guide," it is also necessary in the other.

The two "Guides" differ in that the one devoted to the mammal galleries is the seventh edition, while the other is the first issue; a further difference is to be found in the fact that whereas the names of the authors appear in the second, no such information is afforded in the first. Another point of distinction is the greater prominence given to popular names and the smaller amount of technical detail given in the former than in the latter. In the "Mammal Guide," for instance, the English names of the animals are alone placed under the figures, whereas many of the figures in the "Coral Guide" have only the scientific names, and when English names are given they occupy the second instead of the first place. It is true, as stated in the preface, that it is less easy to avoid the use of technical terms in dealing with the lower invertebrates than when treating of mammals or birds, and popular names are not so readily at hand. We venture to think, however, that more might have been done in this direction than the authors have thought fit to attempt In any case, the substitution of terms like "hairs" for "cilia," "feathery" for "plumose" and "horny" for "chitinous" could be made without any loss of accuracy

and with advantage to the public. It is extraordinary how limited is the vocabulary of a large portion of even the well-educated section of the public; and it is the too free use of technical terms in the better class of popular natural histories which drives people to those of an altogether inferior description. Another point to which we would draw attention in connection with the "Coral Guide" (which, by the way, includes sponges and various other low invertebrates) is the advisability of omitting the names of describers of particular species or structures. Such names as Wyville Thompson, Hickson, Duerden and Shipley are familiar enough to zoological students, but they are quite unknown to the outside public for whom the book is intended.

A feature of the "Coral Guide" is the wealth and beauty of the illustrations, which render it a most wonderful shillingsworth, altogether apart from its high value as an excellent introduction to the groups of animals of which it treats. A number of new illustrations also characterise the seventh edition of the "Mammal Guide," which, for reasons apparent to those in the "know," the present writer is debarred from either criticising or commending. R. L.

TERRESTRIAL MAGNETISM.

AN interesting paper describing the results of an investigation to determine to what extent magnetic disturbances of the needle are connected with the geological conformation of a selected mountainous district has recently been published.[1]

The well-known inquiry into the relation between the magnetic and geological constitution of Great Britain and Ireland conducted by Rücker and Thorpe has been before us for some six years, and in the present paper we have the report of results obtained in another country and in later years having the same object in view.

The region selected for the observations was the Kaiserstuhl, a mountainous district in the neighbourhood of Freiburg in Baden, of which exact topographical and geological surveys had been made, and it is from this source that the maps accompanying the paper and upon which the results of the observations are exhibited were obtained.

The base station was at Freiburg on the spot occupied by Lamont in 1852, but the several observations were compared with a station nearly in the centre of the Kaiserstuhl, at which the magnetic elements were considered normal. In all, 382 determinations of the horizontal force, 140 of the inclination and 137 of the declination were made, and the epoch assigned is 1898·7, but no corrections for diurnal inequality were made. The resulting disturbances from these observations are shown on a special map of "Isanomalen."

The author arrives at the following conclusions:—(*a*) That wherever the geological conformation is of basalt, there he experiences disturbance of the needle partly due to permanent magnetisation of the basalt; (*b*) that the principal disturbances are caused by compact masses of basalt with a North Pole acting vertically upwards—or nearly so—on the north-seeking end of the needle, and the magnetism of these masses is not due to induction from the earth.

With (*a*) we may concur as to a connection being frequently found between the geological formation of basalt and magnetic disturbance of the needle, but it has been also shown that basalt may be present in large masses and certain forms without causing any such disturbance. The conclusion in (*b*) can hardly be accepted, for it is well known that in the northern hemisphere the north-seeking end of the needle is generally attracted downwards by locally disturbing rocks, pointing rather to induction from the earth as the cause of the magnetisation of basalt.

In order to find an explanation of the causes of the observed disturbances of the needle, pieces of basalt were taken from the surface and from a working quarry, and their several effects upon a compass observed, but no information of importance was obtained from the experiments. The question of the effects of lightning on the magnetism of rocks is also discussed, but dismissed as untenable.

It should, however, be remarked that the author does not look for more than general results from the observations as carried out, but they certainly form the nucleus of a further survey from which more definite results might be obtained as to the connection between geological conformation and magnetic disturbances.

Having considered some of the effects of local magnetic disturbance in Germany, we may now turn to the remarkable effects of such disturbance on the magnetic declination in the United States as shown in the latest chart[1] of lines of equal value of that element for 1902.

This chart is a continuation of the series published by the United States Coast and Geodetic Survey, and gives true isogonals for every degree. An examination of the lines shows that some of the most remarkable disturbances occur in mountainous districts, especially in the State of California. With its lines of equal annual change of the declination this chart is decidedly valuable, both from the practical and scientific points of view.

The values of the magnetic dip and declination given in Father Doyle's pamphlet[2] are the result of eight years' photographic record taken at the Manila Central Observatory during the period January 1, 1890, to December 31, 1897. The position of this observatory has been specially selected with a view to avoiding magnetic disturbances either in the locality or the materials of the building. Curves of the mean hourly variation of the declination for each month of the eight years are given, and also curves of the mean annual and mean semi-annual variation of the dip and declination. The chief interest, however, of the data recorded lies in the values of the secular variation of both elements for the epoch 1887–99. In these we have corroborative evidence of the small secular change of the declination, and the large change which is so marked in the dip, which has taken place during the epoch 1880–1900 at the observatories of Bombay, Batavia, Manila and Hong Kong. A chart of the isogonic and isoclinic lines corresponding to the epoch January 1892 for the region comprised between the Philippine Islands and Southern Japan is appended.

THE "NATURE-STUDY" EXHIBITION.

THROUGH the courtesy of the Royal Botanic Society, the aims of which are by no means so purely social as some of its present interests might suggest, a "Nature-Study" Exhibition is now being held in Regent's Park. Never has there been a better undertaking, nor could one be set on foot, which would do more to bring about a rational system of teaching such as is now looked forward to, whereby the pupils may be keenly interested instead of bored and their work made a labour of love instead of a dreary task.

There have long been in this country those who appre-

1 "Erdmagnetische Untersuchungung im Kaiserstuhl," von G. Meyer. (Published in the *Berichte* der Naturforschenden Gesellschaft zu Freiburg i. Br. Band xii., 1902.)

1 "Chart of Lines of Equal Magnetic Declination and Annual Change for 1902." (Published by the United States Coast and Geodetic Survey, February, 1902.)

2 "Magnetical Dip and Declination in the Philippine Islands." Brief notice of the same by Rev. John Doyle, S.J., of the Manila Central Observatory (1901).

ciate the emotional delights and the intellectual pleasures accruing from a first-hand acquaintance with nature, but the magnitude and success of the present exhibition go to show how widely and how well the value of the study which this demands is becoming recognised as a branch of all general education by those more nearly concerned with it than the naturalist.

THE OPENING CEREMONY.

In the first place, the Duke of Devonshire, who presided at the opening ceremony, which was performed by the Duchess of Devonshire on July 23, said that "the new educational departure," as he termed it, had the "very warmest sympathy" of the Board of Education, of which he is the President. In the case of rural education, he continued, the Board had met with a serious difficulty, for if the agricultural labourer does value education at all, it is only too often merely because it enables him to escape from the drudgery of his existence in the country into the more exciting atmosphere of the towns. In these circumstances it is not surprising that country gentlemen and many farmers have not viewed education and educational progress with any great enthusiasm. The Board of Education was consequently very desirous of finding some means by which education, and more especially elementary education, should be brought into closer relation with rural life and with the occupations connected with the cultivation of the land. It also felt the necessity of making all classes connected with the land feel that education is a thing which is not necessarily antagonistic to, but which ought to be conducive to, their interests.

Within the last three years, the Duke went on to say, the Board received the external assistance which they required by the formation of a very influential committee (the Agricultural Education Committee, of which Mr. Henry Hobhouse, M.P., is the secretary) of members of Parliament and county councils, which drew up certain resolutions which were formally laid before the Board of Education and accepted with much pleasure and satisfaction. The Duke of Devonshire then briefly indicated the changes in the elementary education code and in the directory for scientific education which had been made in accordance with the suggestions thus received. He alluded to the publications impressing upon the managers of schools the importance of making education in the village more consonant with the environment of the scholars, and more especially of encouraging children to gain an intelligent knowledge of the common things which surround them in the country. The lack of teachers is being met by the requirement of the Department that "nature-study" from a practical and experimental point of view shall be taken as one of the subjects for the certificate examination. The Duke also referred to the valuable assistance afforded by county councils, and gave it as the opinion of his Board that "nature-study" may with advantage be introduced into all schools, urban as well as rural. In conclusion, although the value of books as representing accumulated knowledge was ungrudgingly allowed, yet in the opinion of the Duke of Devonshire the study of them may too often be only an exercise of memory and may leave almost untouched the other faculties of the mind, while the intelligent observation and study of the facts of nature is a mental discipline which cannot fail to develop those powers of the mind which it is the object of all true education to discover, to cultivate and to strengthen.

THE EXHIBITION.

The number of the exhibits and the fact that all classes of educational establishments have contributed them is another argument in favour of the contention that the appreciation of "nature-study" as a factor in education is no longer confined to a few enthusiasts. The time has passed when one could only say what might be attempted, now one can point to this training college or to that school and say what has been done. The main object of the Association was to bring the movement to this stage and to collect together as many examples as possible of "nature-study" work or of what goes by this name. Teachers who have taken up such teaching would then be able to improve their methods after an examination of others' endeavours, while those in ignorance of how to proceed or apathetic could obtain the information they required or be spurred on to attack a subject so well worthy of attention.

In order that nothing of value might be excluded, the committee admitted anything connected with natural history teaching, and contented itself with making general suggestions as to how this might be represented at the exhibition. It must be said that the immediate results have far exceeded all anticipation. A more detailed consideration of these may be considered in connection with the chief awards that have been made, and this after a third point showing the importance attached to the "nature-study" movement has been dwelt upon. The judges whose names are given below without hesitation signified their willingness to undertake what has proved an arduous task—Profs. Hall, Miall, Lloyd Morgan, Arthur Thomson and Wallace.

In Group A the Boards of Education and Agriculture are exhibiting their leaflets, and most of the agricultural colleges are represented. Seeing how much work has been done by county councils in the training of teachers, but few of them have sent exhibits; Cheshire, Hampshire and Surrey contribute collective exhibits showing the whole educational scheme of each county, and of these Surrey has received one medal for the general exhibit and another for the individual work exhibited by Tiffin's Boys' School Natural History Society properly coming into Group B (secondary schools). A large number of the latter schools of all grades have sent exhibits. Medals have been awarded to the High School, Arbroath, for drawings illustrating natural history; to St. Paul's School, for the work of the School Field Club; to Streatham High School, of the Church School Company, for a nature-study calendar; to James Allen's Girls' School, Dulwich, for the general exhibit, which contains many interesting water cultures of plants; to Bedale's School, Hants, for its scheme of nature-study; and to the Friends' School at Bootham, York, for its general exhibit, which was chiefly that of the Boys' Natural History Society.

Among the numerous elementary schools, the Chislehurst Road Board School, Orpington, Kent, received a medal for its general exhibit, as did the Arnot Street Board School, Liverpool, for its excursion scheme. The only training college similarly recognised was the House of Education, Ambleside, while among the exhibits of private persons and institutions a medal was given to the Stepney Borough Museum. Two American exhibits, namely, those of the New York Natural History Museum and Philadelphia Training College, also received the highest possible award.

A most important result which will possibly accrue from the exhibition will be the determination of what kind of nature-study teaching is to be recognised as such; for this one must look to the report of the Association after receiving the collective and individual expressions of opinion from the judges. Looking, however, at the exhibits which have received medals, it will be seen that they have in nearly all cases shown evidences of outdoor work or practical dealing with living things upon the part of pupils themselves. The fourth piece of evidence as to the value of the exhibition as promoting nature-study is afforded by the position and standing of

those who have taken part in the conferences or have promised to do so. A short account of some of the addresses and papers is given below.

THE CONFERENCES.

Mr. Hanbury, President of the Board of Agriculture, presided at the first of the meetings on July 24 and spoke of the general educational value of nature-study and of the special dependence of agricultural industry upon habits of careful observation. He further pointed out how his Board and that of Education were working in harmony together, and said with regard to those agricultural colleges which have been undertaking the training of teachers that their work ought to be recognised by the bestowal of extra grants by the Board of Agriculture.

Lord Avebury took as the subject of the first address "The Study of Nature." He attributed a most curious ignorance of common things to the fact that great public schools omit the subject altogether, or devote to it only an hour or two in the week snatched from the insatiable demands of Latin and Greek. Oxford and Cambridge have most excellent science schools, but prizes and fellowships are still mainly given to classics and mathematics; degrees are given there, and now, alas! even at the University of London, without requiring any knowledge of the world in which we live. Our universities give excellent teaching, they prepare learned specialists, but are places of instruction rather than of education. Lord Avebury touched also on early specialisation; on the use and abuse of collections; and the various lines along which nature may be studied.

Mr. Henry Hobhouse, M.P., read a paper on "How County Councils may encourage Nature-Study." Their chief work, he said, lies in the direction of training teachers, and this training, though not necessarily a thoroughly scientific one, should impart the elements of certain sciences, and more particularly a knowledge of the best methods of inculcating habits of observation. Mr. Hobhouse summarised what the county councils had already done, and said that much more still remained to be accomplished. As it was not to be expected that every village schoolmistress would be able to teach nature-study, an arrangement would have to be made for peripatetic teachers to visit groups of small schools: school gardens and school museums would also have to be organised. Useful work in the protection of wild birds might be done by holding classes to which gamekeepers might be specially asked to attend, and much economic nature-study could be taken up.

Prof. Geddes was unable to be present, and his paper was taken as read; its vital points are (1) that nature is a moving unity or pageant of the seasons, not an abstract syllabus of "object lessons" or even dissected "types"; (2) that the essential strategic point for the nature teacher is to give the pupil the joy of nature before the intellectual analysis of it; (3) among immediate practical possibilities, and taking excursions for granted, the essential desideratum to be secured for country and suburban schools without delay and for town schools so far as possible is the school garden, always provided this is designed to show to the full, the living seasonal beauty of its chosen plants and be not a cats' graveyard of labels, however orderly. The introduction of a flower border, however small, into the present desert playground is pleaded for on all grounds, moral as well as intellectual and æsthetic.

Prof. J. Arthur Thomson began his most interesting and suggestive paper by quoting the definition of nature-study given by his friend Prof. Geddes, it is "the habit of observing and thinking for oneself and at one's best, without books or helps, in the presence of the facts and in the open air." Prof. Thomson had next a word to say on the danger of doing nature-study teaching badly and distorting the child's outlook on the world. Given a man or woman with the mood of the naturalist, the country schoolmaster who knows and loves the birds, or the country schoolmistress who knows and loves the flowers, then the course of nature-study—now compulsory—is sure to be healthful. Given, however, a teacher who, through overwork, or preoccupation with other disciplines, or lack of early training, is only coercively, not organically, interested in nature-lore, then Prof. Thomson feared that the result would be very bad indeed. The title of the paper was the "Seasonal Study of Natural History," and a sketch of a seasonal course was given, arranged so that the scholars faced appropriate problems at appropriate times. It was argued that the seasonal order and method of study, though not the easiest, was the most natural. It was the most primitive method, yet the exhibits seemed to show that it was capable of being the most evolved. It followed up the pre-school education of the child, and was justified by physiological and psychological facts. Furthermore, the seasonal method worked exceedingly well in practice, being always relevant to what the pupils are seeing and feeling out of school, facilitating the desirable cooperation of the class in securing the specimens for the actual work, and being readily correlated with other school studies.

Mr. H. Coates illustrated the subject of local museums as aids in the teaching of nature with reference to Perth Museum, in connection with which children's essay competitions are most successfully held.

Lord Strathcona, as chairman at the second conference on July 28, gave an account of work in Canada carried out by the generosity of Sir William McDonald, who has given three-quarters of a million of money. Model farms were touched upon, and Lord Strathcona gave a particularly interesting account of his own work in introducing vegetable culture into Labrador, which had previously been unknown.

Prof. Lloyd Morgan had also a definition to give when dealing with nature-study in elementary education. He said that it was "a means by which simple natural objects and processes acquire *meaning*." Like Prof. Thomson's paper, the whole question is so carefully considered that no brief notice could do it justice. The movement which the meeting was to foster and develop, according to the speaker, is part of that reform of educational procedure which has been in progress for many years. One of the points to be regarded is the patchiness of a child's mind, to whom even the beginnings of science are impossible. The teacher, say a scientific botanist, must not, therefore, get tired of fostering the powers of observation and affording facilities for simple investigation, and instead endeavour to inculcate general laws and principles beyond the comprehension of the child. Technical terms where they are simple nouns and not descriptions are allowable, but after reading a long description of the dandelion taken from a nature-study book Prof. Morgan begged his hearers to stop before they got to "anthers syngenesious."

Mr. Franklin dealt with how to bring children into touch with nature, and the work of the Leicester School Board was described by Mr. Major. Miss Mary Simpson, in speaking of the teacher as an observer, suggested that if the teacher had reached that stage most of the difficulties would be gone. Finally, at this meeting, which during the latter half was presided over by Sir Joshua Fitch, Mr. John Evans urged the advantages of using trees as a means of nature-study.

On Tuesday, July 29, the chair was taken by the Lord Balfour of Burleigh, K.T., Secretary for Scotland. He gave an account of the excellent progress of the "nature-study" movement started several years ago across the border. "Nature-study," he said, must be rather looked upon by the children as recreation; their minds must not be filled with facts, but must be taught to make observations and to investigate. If this were done it would redound to the credit of education in all countries.

Mr. Choate, the American Ambassador, in introducing Prof. Albert Bickmore, of the Natural History Museum, New York, added the weight of his testimony to the value of the work in hand. After this Prof. Bickmore briefly explained his methods of visual instruction, at first geographical and now combined with nature-study; and after the conference in the club-room the audience adjourned to the museum in the gardens to see a series of views thrown upon the screen with the lantern to illustrate further Prof. Bickmore's methods, with children, older scholars, university students and teachers. He began his work with a class of 28, and last winter the attendance at his lectures was 26,910.

Mr. Herbert Morrell, M.P., brought forward many trenchant and amusing examples of the value of "Nature-Study in relation to Rural Pursuits."

Prof. Hall, of Wye College, in defining the "Proper Attitude of the Teacher," had some excellent points to lay before his hearers. He appeared, however, to think, contrary to others interested in the subject, that "facts" must be accompanied by "ideas," which brings it near to elementary science teaching. The subject taken from the standpoint of a teacher in an elementary school and considered in a paper by Mr. G. H.

Rose, headmaster of Caterham Board School, has much in it that others less nearly connected with the work might fail to recognise, and will prove well worthy of careful examination when it is printed.

The remainder of the programme is as follows:—

Thursday, July 31, chairman, Sir George Kekewich, K.C.B., Secretary to the Board of Education. Address on "Nature-Study in Colleges and Higher Schools," by Prof. Miall, F.R.S. Selected speakers:—"Nature-Study in Girls' Secondary Schools," Miss Mary Gurney; "Plant Life as Nature-Study," Mr. Scott Elliott; "School Gardens," Mr. T. G. Rooper; "Geology as a Branch of Nature-Study," Prof. Grenville Cole.

Friday, August 1, chairman, the Right Hon. Sir W. Hart-Dyke, Bart., M.P. Address on "The Training of Teachers in Nature-Study," by the Rev. Canon Steward. Selected speakers:—"The Relation of Nature-Study to School Work and to the Home," Sir Joshua Fitch; "Nature-Study as an Element of Culture," Mr. M. E. Sadler; "School Rambles and the Training of Teachers," Mr. J. H. Cowham; "The Present Work of the County Councils," Mr. H. Macan.

In conclusion, it must be said that the work of bringing the undertaking to such a successful issue has taken the whole time and energy of Mr. J. C. Medd, the honorary secretary, who has had at his disposal the great experience and the marvellous tact of Sir John Cockburn, the chairman of the Association; Mr. Cundall, of the Victoria and Albert Museum, Mr. A. T. Simmons and Mr. A. Taylor, H.M. sub-inspector, to whom the task of arranging the exhibits was allotted, must also be given a full measure of praise. WILFRED MARK WEBB.

NOTES.

THE members of the new Order of Merit were entertained at dinner by the Athenæum Club on Friday last. Science was represented by four of the twelve members of the Order—Lord Rayleigh, Lord Kelvin, Lord Lister and Sir William Huggins. Lord Avebury (trustee of the club) presided, and among other members present were many leaders of science, art and literature.

A NEW laboratory for the study of experimental psychology has been instituted at King's College, London. The laboratory will be in charge of Dr. W. G. Smith, under Prof. Halliburton's general supervision.

THE *Times* states that during her passage from Kronstadt to Kiel the Italian cruiser *Carlo Alberto* carried out some important experiments in wireless telegraphy under the personal direction of Mr. Marconi. Signals were exchanged with stations 2000 kilometres distant, 1000 kilometres by sea and 1000 kilometres by land.

PROF. F. A. FOREL writes from Morges to say that he has made inquiries into the report that after a shower of rain at Frauenfeld, Canton Thurgau, Switzerland, the ground was covered with a thin layer of ashes of greyish-blue colour (p. 306). A teacher of natural history at Frauenfeld has informed him that the news was misleading and that the dust was not of volcanic origin.

A TELEGRAM from Kingstown, St. Vincent, states that there have been two slight eruptions of the Soufrière volcano since July 21, and an earthquake in the north-eastern part of the island. The cable steamer *Newington*, which is working eighteen miles to the north, reports that the depth of the sea has increased in that locality to a mile and a quarter.

THE *Daily Mail* correspondent at Madrid reports that two large cliffs near the town of Calataynd, in Aragon, have fallen down, destroying several houses and injuring many people. A crater has opened in the Pico de Europa mountains, which separate the provinces of Santander and Asturias. A great column of vapour is issuing therefrom, and the people are in a state of alarm, fearing a volcanic eruption. A Central News despatch from the Azores states that there has just been a terrific submarine volcanic eruption off Horta. Masses of rock in a state of incandescence were thrown up, and the people became panic-stricken. A Reuter despatch from San José, Costa Rica, states that there has lately been unusual activity among the Costa Rican volcanoes, considerably affecting the land in the neighbourhood of Terraba. From New York another Reuter despatch records that an earthquake shock was felt shortly after midday on Monday, July 28, in parts of Nebraska, Iowa and South Dakota, but no damage was done. Three shocks have also occurred in the Lompoc Valley, California, since Sunday evening, July 27. Cracks appeared in the earth and there was widespread panic among the inhabitants. Vibrations have also been felt at other places in California.

THE *Westminster Gazette* on Saturday last devoted a column and a half to the Armstrong-Orling system of wireless telegraphy. We have referred on two or three occasions to this system, the receiving apparatus of which was described in these columns last December. We now understand that a company is about to be registered to manufacture and supply the transmitters and receivers. It is stated that apparatus has been worked out suitable for wireless signalling up to a distance of twenty miles, the ground being used as a conductor, and that it will be sold, at a very cheap rate, for private installations. Details of a technical nature are, however, entirely wanting, and without these it is impossible to form any opinion of the system. So far as we know no description of the transmitter has been published, although we were told eight months ago that it was proposed to read a paper upon it before one of the scientific societies. We have also consulted the patent files, but there is nothing in Mr. Orling's name as yet printed which is specially novel or remarkable. It is therefore advisable to wait until further particulars are available before deciding whether the "programme of amazing promise" sketched in the *Westminster Gazette* is likely to be realised.

WE regret to see the announcement of the death of the Rev. Charles E. Searle, master of Pembroke College, Cambridge, and formerly college lecturer in mathematics.

IN the House of Commons on Monday, Mr. J. A. Dewar asked whether it could be made a condition of the annual grant of 15,300*l.* to the Meteorological Council that the high-level and low-level observatories at Fort William should be kept in a state of efficiency, or whether an additional contribution towards the expenses of properly maintaining these observatories would be considered. In reply, Mr. Balfour said he had been advised it would not be desirable to impose conditions on the Meteorological Council or to inquire into this or that particular observatory. He was not prepared to give an answer to the last part of the question.

THE decision to close the observatory on Ben Nevis was discussed at the general meeting of the Scottish Meteorological Society, held in Edinburgh last week. Lord Maclaren, who presided, said that the observatory would have to be closed because there were no funds available for carrying on the work. He thought it was a case for inquiry, and if the Government appointed a committee to take evidence, probably the difficulties would be overcome. Sir John Murray, as one of the original directors, said it was not their intention to found a permanent institution, but only to make an experiment of high-level observations. The experiment had been most satisfactory in every respect. But the observatory must now be closed unless one of two things happened; either the State must take over

the observatory, or the directors must be put in possession of 12,000*l.* worth of consols to enable them to carry it on for another meteorological cycle.

PRINCE AUGUSTE D'ARENBERG, president of the Suez Canal Company, has sent a letter to the president of the Liverpool School of Tropical Medicine asking for the cooperation of the school in a concerted effort to cope with the prevalence of malaria in Ismailia, and making a formal request for the services of Major Ronald Ross, C.B., F.R.S., to start operations there against mosquitoes. The committee of the school has acceded to the request, and is making arrangements to enable Major Ross to proceed to Ismailia in September next, when malaria is especially prevalent. Major Ross will begin by starting an organised campaign against malaria, and will go out again later in the year to carry it through.

THE Prince of Wales has consented to act as president of the fund which has been established for the purpose of conducting research into the nature, causes and cure of cancer. The vice-presidents of the fund are the Lords Lister and Strathcona, the Right Hon. Arthur Balfour, Sir Frederick Bramwell, Sir William Broadbent and Mr. Bischoffsheim. The executive committee is composed of Sir W. Broadbent, Sir W. Church, Sir H. Howse, Drs. Sydney Martin, Pye-Smith and Rose Bradford, Prof. Sims Woodhead, and Messrs. Langton, Henry Morris, Butlin, McFadyean and Watson Cheyne. The money contributions actually paid amount to 32,391*l.*, and promises of 4100*l.* more have been received, making a total of 36,491*l.* towards the full amount of 100,000*l.* originally asked for. Work will be commenced with the sum in hand, but it is hoped that the full capital required will be subscribed.

NATURAL science in Ceylon has sustained a severe loss by the untimely death of Mr. Oliver Collett, F.R.M.S., who, while carrying on actively his vocation as a tea planter, found time for excellent original work both in the field and laboratory. He devoted himself especially to the Mollusca; and a genus and several species of land shells bear his name. As a member of the Ceylon branch of the Royal Asiatic Society he contributed various papers on zoological questions. He also brought his scientific knowledge to bear on some economic questions in connection with the cultivation of tea, and was much esteemed by his fellow planters, being at the time of his death chairman of the local Planters' Association. Mr. Collett, who was thirty-five years of age, possessed a very attractive personality, and many, both at home and in Ceylon, who were brought in contact with him by common interests, deplore the loss of a charming friend and an enthusiastic naturalist. He died on June 13 somewhat suddenly at Colombo, from an attack of dysentery.

A MEETING of the Institution of Mechanical Engineers was held at Newcastle on Tuesday and Wednesday, July 29 and 30. Among the papers down to be read were:—"Liquid Fuel for Steamers," by Mr. E. L. Orde; "Some Experiments on Steam-Engine Economy," by Prof. R. L. Weighton; "Pumping Plant for Condensing Water," by Mr. Charles Hopkinson; "Mechanical Appliances in Mines (Drilling and Coal Cutting)," by Mr. R. H. Wainford; "Recent Developments in Pneumatic Tools and Appliances," by Mr. Ewart C. Amos; and "Motor Cars of 1902," by Captain C. C. Longridge.

A FEW weeks ago (July 3, p. 227) we gave a short account of the investigations into the connection between the magnetic currents in the earth and the Aurora Borealis, which Prof. Kr. Birkeland conducted in the winter of 1899–1900 at two stations Talvik and Haldde, on the summits of two mountains to the west of Bossekop, Altenfjord, in Lapland. Prof. Birkeland recently left Christiania for Archangel in order to start from there on July 23 and proceed to Matoschkin Strait, Nova Zembla, to organise and set in working order a similar station and leave it in the hands of four observers before returning to Norway. At Bossekop, where observations will also be made, the observatory is admirably situated on the summit of Haldde Mountain; for at the base a tunnel belonging to a copper-mine runs for 250 metres into the mountain, and registering apparatus can be set up in it. Simultaneous observations can thus be made on the electrical currents in the atmosphere and in the earth. The third station will be on Axel island, Spitsbergen. A fourth station, with two observers, will be at Dyrafjord, Iceland, and researches will be carried on for about a year at all of them. In order to supplement his own observations and compare them with others, Prof. Birkeland has invited more than a hundred magnetic and meteorological observatories to make simultaneous observations, and has received promises of co-operation from many of them.

WRITING from St. Petersburg on July 22, Mr. J. F. Baddeley gives in the *Times* a few details of a serious glacier disaster in the Caucasus, news of which has been received from Vladikavkaz. Between Mont Kazbek and Ghimarai Khokh a glacier descends into the narrow wedge-shaped valley of the Ghenal Don, which, after a course of about thirteen miles, nearly due north, joins the Ghizel Don, a tributary of the Terek. Like most of the glaciers in the Caucasus, that of the Ghenal Don has of late years receded considerably, and some thirty years ago copious springs of hot sulphur water were uncovered, which had formerly made their presence known by the steam that forced its way through the ice. About the middle of July the end of the glacier suddenly broke off and slid down the valley, causing the loss of thirty-two lives. On July 19 another huge block of ice broke off and followed the first with terrible rapidity for eight miles down the Ghenal Don. Similar catastrophes have frequently occurred on the Georgian Road, in the valley of the Terek, owing to icefalls from the Devdoraki Glacier, north and slightly east of Kazbek; but Mr. Baddeley says he has not met with any mention of previous cases in connection with the Ghenal Don.

EVIDENCE that the competition of the electrical tramway is making itself seriously felt is afforded by the fact that the North-Eastern Railway Company has decided to start working some of its local lines near Newcastle-on-Tyne electrically, and has already invited tenders for the electrical equipment of the sub-stations, permanent way and coaches. It is also reported that the Lancashire and Yorkshire Railway Company is about to make a practical test of electrical running on one of its branch lines near Manchester.

A RECTIFIER for alternating currents devised by Messrs. G. H. Morse and C. R. Cushman is described by the former in the New York *Electrical World and Engineer* for July 19. An electric arc is burnt between three carbon points which are placed in a strong magnetic field; the arc burns between the upper carbon and one or other of the lower carbons, according to the direction of the current. The alternating current is thus divided into two pulsating direct currents, and experiments have shown that, with a proper adjustment of the strength of the magnetic field, the length of arc, &c., the rectification can be made practically complete; that is to say, two direct currents can be obtained each equal to half the alternating current.

ELECTROCHEMISTRY has made enormous strides on the continent and in America. But chemists and electricians in this country have, for some reason best known to themselves, shown a want of interest which is absolutely astonishing. Almost every university and technical institute in Germany has

an electrochemical laboratory, or if there is no special laboratory at least the subject is taught, and the same may be said of America. France also is making considerable headway in the teaching of electrochemistry. Here in this country the whole subject has been practically ignored. In order to try to bring the claims of this very important science before the scientific world and to interest manufacturers in electrochemistry, a small committee of electricians and chemists has been sitting since March in order to see whether it would not be possible to form a British Electrochemical Society. A fair amount of support has been promised, and the committee is now sending out circulars inviting cooperation in the formation of the proposed society. It is to be hoped that there will be a ready response to the invitation, so that all who are interested in electrochemistry may combine their efforts to promote its advancement in this country.

INTERNATIONAL balloon ascents were made on the morning of March 6 in France, Germany, Austria and Russia, and kites were also sent up by Mr. Rotch at Blue Hill, Boston, U.S.A., on the previous evening. The following are some of the preliminary results of the highest unmanned ascents:—Itteville (near Paris), temperature at starting, 2°·8 C.; greatest height reached, 14,000 metres; lowest temperature recorded, − 67°·0. Strasburg, temperature on ground, − 0°·4; at 9300 metres, − 54°·0. At Blue Hill the kites ascended through a thick snowcloud; the lowest temperature, − 7°·0, was recorded at a height of 1658 metres; above this the temperature rose, and at a height of 2000 metres it reached − 2°·4. Over Europe an area of high barometric pressure prevailed, while at Blue Hill the kite rose on the north-west side of a deep depression, the centre of which lay over the Atlantic.

THE results of the meteorological observations made at the Rousdon Observatory, Devon, during the year 1901 have been published by the Hon. Lady Peek. The observations have been regularly made, as hitherto, by Mr. C. Grover, and the tables have been prepared for publication under the supervision of Mr. W. Marriott, assistant secretary of the Royal Meteorological Society. The volume also contains an account of damage done by lightning to a room occupied by two persons on the night of June 29–30. The results of this valuable series of observations for the years 1884–1900 are discussed by Dr. J. Hann in the current number of the *Meteorologische Zeitschrift*, chiefly from tables given in the previous volume (1900). In this discussion Dr. Hann lays stress on the advantage of calculating the mean monthly and yearly extremes of temperature and pressure instead of merely quoting the absolute extreme readings, because the latter may only refer to any one of the years under discussion, and are not comparable with the results of a series of years.

AN interesting instance of that adaptability to changing tastes and conditions which is the mainspring of progress in industry as well as in science is afforded by a note in the *Journal* of the Society of Arts (July 18). For some years the demand for claret has greatly diminished in favour of the wines of Champagne, and has seriously affected the wine industry in the Bordeaux district. Several proprietors in the Médoc have, however, now commenced the production of sparkling wines by the same process as champagne is made, and their action has been the means of developing practically a new industry. It may at first seem strange that white wine should be able to be made in the Médoc, where only black grapes are grown, but as a matter of fact champagne is almost entirely made from black grapes, and the most celebrated vineyards in the Champagne district are all planted with them. The colour of the wine depends only on the way in which the wine is made. All the colouring matter is in the skin, while the fruit itself is colourless, or nearly so. If the whole of the grape, skin and all, be allowed to ferment together, the colouring matter in the skin will be dissolved in the juice of the grape, and the wine produced will be red. If, on the contrary, the skin be removed before the fermentation begins, the wine will be white. Sparkling wines require much more working and preparation than still wines, and a second fermentation has to take place when the wine is in bottle, and it is this which gives the gas. The wine has to pass through a long series of operations, which have to be carried out, from first to last, under a perfectly even temperature. For this reason, the cellars in the Champagne district are dug out often to a great depth in the chalk. It would have been impossible to find such cellars in the Médoc, where the soil is of a gravelly nature, but at Bourg, on the right bank of the Gironde, opposite the Médoc vineyards, there are cliffs of Oolitic limestone, whence the stone has for centuries been quarried. The stone has been quarried out in long galleries, which are now adapted for cool cellars, with a perfectly even temperature all the year round, and in these the sparkling médoc is made in identically similar circumstances to the wines of Rheims or Epernay. It is stated that to the ordinary taster there is nothing but the label to distinguish the sparkling médoc from the best brands of champagne. Another white sparkling wine is made at St. Emilion, and the cellars are in the caves below the ruins of an old monastery, from which the wine takes its name.

IN a note contributed to the *Atti dei Lincei*, xi. (1) 10, by Signor E. Daniele, dealing with certain particular cases of motion of a point in a plane, we notice the following interesting conclusion:—"In the motion of a point under a central force, the trajectories can be divided into an infinity of isothermal orthogonal systems, when the force is proportional to any power of the distance."

THE theory according to which the properties of colloidal substances are attributed to particles in a fine state of suspension is advanced by Dr. J. Billitzer in a recent communication to the Vienna Academy (*Sitzungsberichte*, No. 9). The author starts with the assumptions that we have to deal with a fine suspension and that the particles of this are oppositely electrified to the fluid. From these hypotheses numerous important conclusions are derived, and an attempt has been made to answer the principal objections to the theory.

A MATHEMATICAL investigation of the principles of the seismograph is given by Dr. M. Contarini in the *Atti dei Lincei*, xi. (1) 10. In this paper the author passes from the problem of the motion of a chain of rigid bodies, the first of which is fixed to the ground by at least one point, to the special case of two bodies only. It is shown how with such a system it is possible to determine four out of the six components of the seismic disturbance. For the other two components an instrument resembling the Vicentini microseismograph may be used.

THE question as to whether bats are capable of transmitting bubonic plague is discussed by Dr. B. Gosio in the *Atti dei Lincei*, xi. (1) 10. During a recent small epidemic at Naples it was suspected that the disease emanated from a building completely isolated by walls from the town, and with separate drainage, and the idea suggested itself that the infection must have been carried by the numerous bats that were constantly flying around the building. Dr. Gosio accordingly made experiments by inoculating specimens of *Vespertilio noctula* with doses of the virus varying from 0·5 c.c. to 0·05 c.c. of cultures developed for twenty-four hours. The result was that in every case the bats contracted the disease and died in a comparatively short interval, and on examination all the organs of the dead animals were seen to be rich in germs. It is suggested that the

numerous parasites with which the bat is commonly affected may be the means of propagating the germs, and this view is confirmed by experiments previously made in the author's laboratory on the common flea. A further confirmation is afforded by the observation that subcutaneous injections of infected matter, even in small quantities, are sufficient to transmit the disease to bats.

THE *Zoologist* for July contains but two papers, the one, by Dr. A. G. Butler, on birds in captivity, the other, by the Messrs. Ticehurst, on birds met with in Finmark.

THE "corallines," or calcareous algas, of Japan form the subject of a memoir by Mr. K. Yendo in the second part of vol. xvi. of the *Journal* of the College of Science of Tokyo, the other two articles in the same issue being also devoted to botanical subjects.

IN the first part of vol. lxxii. of the *Zeitschrift für wissenschaftliche Zoologie*, Herr E. Schultz continues his studies in "regeneration," taking as his text the turbellarian worms. The superficial nerve-cells in the spinal chord of birds and reptiles form the subject of an article in the same journal by Herr A. Kölliker.

To the *Aarbog* of the Bergen Museum for 1902, Mr. J. A. Grieg contributes a review of the echinoderms of northern Norway; while Mr. H. Friele describes the molluscs obtained during the cruise of the fishery steamer *Michael Sars* in the North Sea during the summer and autumn of 1900. In the latter paper several new forms are named. A third article, by Mr. H. H. Gran, forms the continuation of a memoir on marine bacteria.

IN a memoir on a new generic type (Gephyrocrinus) of crinoid dredged by the Prince of Monaco at a great depth in the Atlantic, the authors, Messrs. Koehler and Bather, state that it is allied to Hyocrinus, represented by a single species obtained by the *Challenger*. Only one specimen, and that imperfect, of the new form was obtained. The paper is published in vol. xv. of the *Mémoires* of the French Zoological Society.

FROM an article in the *Egyptian Gazette* we learn that the additions to the Zoological Gardens at Ghizeh during May and June were seventy-six in number, and include many very valuable and rare animals. Nearly all are natives of the Nile Valley except four Capuchin monkeys from South America, received in exchange, and a specimen of the two-humped Bactrian camel, which has been purchased and delivered in Egypt through the assistance of Dr. Büttikofer, the well-known Swiss naturalist, now Director of the Rotterdam Zoological Gardens, where this species of camel is bred with success. In Egypt, where the one-humped camel is so well known, it is specially interesting to be able to see a specimen of the two-humped camel, and to the native visitor it is perhaps the most astonishing animal in the menagerie.

AT a special memorial meeting held on April 25 of this year under the joint auspices of the Natural History Society, the Teachers' School of Science and the University of Boston (of which an account appears in vol. xxx. No. 4 of the *Proceedings* of the first-named society), addresses were delivered in commemoration of the work of the late Prof. A. Hyatt. According to the inaugural address, Hyatt was born at Washington in 1838 and died suddenly at Cambridge, Mass., in January of the present year on his way to attend a meeting of the Boston Natural History Society, of the museum of which he was so long curator. Hyatt "was professor of zoology and palæontology at the Massachusetts Institute of Technology from 1870 to 1888, and professor of biology at Boston University from 1877. He was the founder of the seaside laboratory at Annisquam, and took the leading part in the foundation of the Teachers' School of Science and of the American Society of Naturalists."

ONE evening in the autumn of last year, while strolling on the beach of a small watering-place near Christchurch, New Zealand, Dr. A. Dendy picked up a small gelatinous object thrown up by the tide. On examination this object turned out to be a relatively large pelagic hydroid polyp. When found it was in a moribund condition, and the body was seen to be covered with a number of medusæ in various stages of development. A full account of this remarkable organism is given by its discoverer in the July issue of the *Quarterly Journal of Microscopical Science*. The organism, which is endowed with free-swimming power, indicates an entirely new type of hydroid, for which the name *Pelagohydra mirabilis* is proposed. Structurally it comes nearest to the aberrant Corymorpha. "It is a very curious fact," remarks the describer, "that two distinct genera of tubularian hydroids agreeing in such striking anatomical peculiarities should have become adapted to two such different modes of life, the one (Pelagohydra) swimming freely in the open ocean, and the other (Corymorpha) rooting itself in the sand at the bottom. . . . So far as I am aware, there is no other hydroid yet known which has become specially adapted to a pelagic mode of life."

A NEW popular edition of Mr. Oliver G. Pike's pleasantly written book entitled "In Bird-Land with Field-Glass and Camera" has been published by Mr. T. Fisher Unwin. The book is illustrated by eighty-three reproductions of photographs of birds and nests taken direct from nature by the author. A notice of the original edition, with one of the illustrations, appeared in NATURE two years ago (vol. lxii. p. 418).

MR. HENRY FROWDE will publish shortly the first instalment of the "Tebtunis Papyri" found by Dr. B. P. Grenfell and Dr. A. S. Hunt at Ûmm el Baragât in the south of the Fayûm and edited by them, with the assistance of Mr. J. Gilbart Smyly. This volume deals with the papyri in which the mummies of crocodiles were wrapped, and they date from the end of the second or the early part of the first century B.C. Mrs. Hearst supplied the funds for the excavations on behalf of the University of California, and this volume inaugurates a series of publications by the University dealing with Egyptian archæology. The book is being issued conjointly by the Egypt Exploration Fund to subscribers to the Græco-Roman branch.

IN the July number of the *Moniteur Scientifique*, Prof. Zinno describes a synthesis of tartaric acid suitable for the production of this substance on the large scale. The method consists in passing a current of carbonic acid gas under a pressure of about three atmospheres over potassium glycerate, the reaction being very similar to that of Kolbe by which sodium salicylate is produced. Potassium glycerate is easily obtained by oxidising glycerin by means of lead dioxide or minium and nitric acid, and then adding to the boiling solution of the lead salt potassium carbonate. Numbers are given in the paper which show that cream of tartar can be produced by this method at a cost which should justify the commercial development of the process.

THOSE who are interested in the sulphuric acid industry will find a noteworthy series of articles bearing upon the subject in the July number of the *Moniteur Scientifique* under the title "Grande Industrie Chimique." The first of these, by Messrs. Niedenführ and Luty, is entitled "A comparative economic study of the manufacture of sulphuric acid by the anhydride and the modern lead chamber processes." Much interesting matter is contained in the paper, and the authors arrive at the conclusion that at the present time the lead chamber processes, when conducted properly, are considerably more economical than the

contact processes, so far as the production of acids which are not very concentrated is concerned. For the manufacture of the strongest acids, however, numbers are given which indicate that the contact process is considerably superior to the older process from the commercial point of view. The other articles on the subject deal with more recent alterations which have been made in the lead chamber process, the theory and practice of sulphuric acid manufacture and the treatment of platinum residues.

THE additions to the Zoological Society's Gardens during the past week include a Side-striped Jackal (*Canis lateralis*), a Young Leopard (*Felis pardus*), a Spotted Hyæna (*Hyaena crocuta*), a Harnessed Antelope (*Tragelaphus scriptus*), a Nagor Antelope (*Cervicapra redunca*), a Marabou Stork (*Leptoptilus crumeniferus*), a White-necked Crow (*Corvus scapulatus*), a Spur-winged Goose (*Plectropterus gambensis*), two Red-backed Pelicans (*Pelecanus rufescens*) from Gambia, West Africa, presented by Captian Sir George C. Denton, K.C.M.G.; a Striped Hyæna (*Hyaena striata*) from Gambia, West Africa, presented by Captain MacCarthy Morrogh; a Black-eared Marmoset (*Hapale penicillata*) from South-east Brazil, presented by Mrs. Armyn Thornton; a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, presented by Miss Ellen Cull; a Red-winged Parrakeet (*Ptistes erythropterus*) from Australia, presented by Miss E. P. France; a Pale-headed Parrakeet (*Platycercus pallidiceps*) from Australia, presented by Mr. Thomas Morson; a West African Python (*Python sebae*) from West Africa, presented by the Rev. H. Ross Phillips; two European Tree Frogs (*Hyla arborea*), European, presented by Mrs. Sidney Wolton; a Thar (*Hemitragus jemlaica*), a Yak (*Poephagus grunniens*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN AUGUST:—

August 1. 15h. 25m. to 19h. 8m. Transit of Jupiter's Sat. III.
4. 11h. 34m. to 16h. 29m. Transit of Jupiter's Sat. IV.
5. 5h. Jupiter in opposition to the sun.
8. 12h. 38m. Minimum of Algol (β Persei).
10. 8h. 29m. to 9h. 32m. Moon occults δ Libræ (mag. 5·3).
10. 8h. 41m. to 9h. 35m. Moon occults α Libræ (mag. 3·0).
11. 9h. 27m. Minimum of Algol (β Persei).
11–12. Maximum of the Perseid meteoric shower.
15. Venus. Illuminated portion of disc = 0·886. Mars = 0·965.
18. 17h. 1m. to 17h. 22m. Moon occults c^1 Capricorni (mag. 5·2).
28. Saturn. Outer minor axis of outer ring = 16″·48.
30. 4h. 37m. to 8h. 20m. Transit of Jupiter's Sat. III.
31. 11h. 10m. Minimum of Algol (β Persei).

A NEW ALGOL VARIABLE.—Prof. Pickering announces the discovery of a new Algol variable (+43°·4101) by Mrs. Fleming, at the Harvard College Observatory.

Two plates, taken with the 8-inch Draper telescope on March 7, 1900, and April 3, 1902, respectively, were being examined in order to discover, if possible, a trace of the image of Comet 1902 *a* on the latter plate. This search was unsuccessful in its immediate object, but Mrs. Fleming noticed that the image of a faint star, the position of which for 1900 was R.A. = 21h. 55·2m., Dec. = +43° 52′, showed a variation in magnitude during the interval between the taking of these two plates, and on examining more plates it was found that generally the light was bright and constant, thus showing the star to be of the Algol type.

The period is about 31·4 days, and the star retains its maximum brightness (photographic magnitude = 8·9) for twenty-eight days and then decreases to minimum by the following steps:—9·0 m. at 1·05 d. before minimum, 9·5 at 0·94 d., 10·0 at 0·84 d., 10·5 at 0·71 d., 11·0 at 0·58 d., and 11·5 at 0·43 d. The light then remains constant at 11·6 m. for more than half a day. The times of increase are apparently the same as those of decrease, but this is not conclusively indicated. (*Astrophysical Journal*, No. 5, vol. xv.)

SPECTROSCOPY OF THE SOLAR ECLIPSE OF MAY 18, 1901.—In No. 5, vol. xv. of the *Astrophysical Journal*, Mr. W. J. Humphreys gives an account of the United States Naval Observatory Eclipse Expedition to Sumatra last year, and a reduction of the spectrograms obtained.

Excellent photographs of the corona were obtained, the cœlostat used having a mirror at either end of its heavy polar axis, one supplying the light to the coronagraph, the other to the spectroscope.

The concave grating used was of 30 feet focal length and had a diffracting surface 8 inches long and 5 inches wide; the whole of this area was not used, however. To obtain good uniform focus heavy celluloid films were used, and these were 2½ inches wide and 36 inches long.

Six films were exposed, and the reductions of the spectra are set out in tabular form, 330 lines between λ 3118 and λ 5204 having been measured. Neglecting those due to hydrogen and helium, the lines are chiefly those belonging to the Mendeléeff series which terminates with the Fe, Ni, and Co groups.

Incidentally observing the shadow bands, Mr. Humphreys found that they were stationary at first, but another observer noted that afterwards they widened out and then attained an increasing velocity.

Mr. Humphreys concludes his report with some useful suggestions which might be profitably considered by future eclipse observers.

REPORT OF THE CAPE OBSERVATORY FOR 1901.—Sir David Gill, in this report, announces the completion and official inauguration of the 24-inch "Victoria" telescope presented to the observatory by Dr. Frank McClean.

The transit circle has been completed and effectively mounted, the house being of a semi-cylindrical form, of which the two halves may be drawn aside at right angles to the axis when observations are to be taken. Owing to the loose nature of the upper rocks, the standard azimuth marks have had to be placed on the surface of the solid rock at the bottom of shafts some 30 feet deep, from which the marks are reflected to the instrument. The heliometer has been cleaned and repaired, and observations of the oppositions of Mars, Jupiter and Saturn have been made. Some thirty observations of the distances and position angles of Jupiter's satellites have also been completed.

The equatorials have been used for observing the phenomena attending ninety-seven separate occultations, to observe Giacobini's comet and the great comet of 1901, and to seek, without success however, for Encke's comet. Thirteen previously unrecorded double stars have been detected by Mr. Innes, the most interesting of them being τ_2 Lupi, ♄ 4625 (chief star) and C.G.A. 2861. The 7-inch equatorial has been used for the revision of the C.P.D., and incidentally the unsuspected variability of the following stars has been detected:—C.P.D. −51°·2275, anonymous, Cor. D.M. −22°·14789, the ranges of variability being from 8·6 m., 9·8 m. and 9·4 m. to invisibility respectively. The character of the second star is not completely known yet, but it is suggested that it may be a Nova, R.A. = 11h. 14m. 14s., Dec. = 61° 10′ S. (1875).

The geodetic work has been actively prosecuted throughout the year, the geodetic arc of meridian having now been carried to the Zambesi, and an effective service of time signals has been distributed throughout the Colony.

WORK AT THE ATHENS OBSERVATORY.[1]

YEARS ago, under the vigorous direction of the late Prof. Schmidt, the Athens Observatory acquired a distinction that was denied to some kindred institutions more favoured with instrumental equipment and substantial endowment. Since that time evil days have fallen on the National Observatory of Greece and its record of useful work has been broken; but it is now a pleasant task to record that a period of renewed activity appears likely to make itself felt in the future conduct of this ancient centre of scientific work. The third volume of the

[1] "Annales de l'Observatoire National d'Athènes." Publiées par Démétrius Eginitis, Directeur de l'Observatoire. Tome iii. Pp. 376. (Athènes: Imprimerie Royale Raftanis-Papageorgiou, 1901.)

"Annales," which has just appeared, devoted mainly to meteorological and climatic inquiries, is perhaps of a modest character viewed from a scientific standpoint; but it shows that the present director, M. Eginitis, is alive to the importance of creating a broader scientific interest throughout the country, which may be productive of greater energy and lead to the establishment of a well-supported institution. If this be the intention of the director, the means he has employed are excellent. For M. Eginitis has endeavoured to interest a number of the better instructed class, such as civil engineers, professors of mathematics in the colleges and schoolmasters, in meteorological and seismological inquiries, and has induced the Government to provide a simple instrumental equipment at stations where it could be properly employed. The result is that he has distributed throughout Greece and the Ionian Isles a number of centres whence climatic observations are regularly forwarded to the central observatory at Athens and there reduced.

The results for the years 1894-9 are printed in this volume, and we regard the fact that the dormant energies of a large number of people are interested, and the habit of continuous observation encouraged, as of greater importance than the actual observations collected. The public is being trained to expect a certain amount of scientific work from the Government officials, and demands for a further advance will be made and will be granted, when urged by competent observers backed by a growing scientific opinion. We would urge M. Eginitis steadily to pursue the methods which he has introduced, and which cannot but be productive of a lasting and beneficial result.

Two memoirs from the director accompany the volume, one a discussion of the observations of meteors made at the observatory, the other on the distribution of earthquakes throughout the day and year as recorded at the Grecian stations. In 1899, M. Eginitis reports 567 earthquake shocks, of which 271 occurred in the spring against 62 in the summer months, and this peculiarity is in general agreement with a more extended inquiry embracing the period 1893-8. With regard to the relative position of the earth and moon, in which the latter might be presumed to have some slight effect in displacing the arrangement of internal rocks as the consequence of a tidal flow, M. Eginitis finds that there is no noticeable connection between the frequency of seismic disturbance and the position of the moon in its orbit. A description of the effects experienced on the occasion of the earthquake at Triphylie on January 22, 1899, concludes this section.

VIBRATIONS OF BRIDGES.

THE last volume issued by the Earthquake Investigation Committee of Japan published in a foreign language is "On the Deflection and Vibration of Railway Bridges"—a subject which, although not seismological, is an excellent illustration of investigations which seismologists have been tempted to pursue.

The author, Dr. F. Ōmori, experimented on twelve railway bridge girders, the spans of which varied between 20 and 200 feet. The instruments used to record the bridge vibrations were a pair of seismographs such as are used for recording horizontal motion, and a horizontal lever seismograph for vertical motion. This latter instrument is here called a *deflectometer*. The quantities measured were the *deflection* of girders, or the total amount of bending caused by the passage of rolling stock, and the vertical transverse and longitudinal *vibrations*, which latter are almost *nil* when the speed of a passing train is either very slow or at a maximum, when the speed has a certain value. The incentive to this work was a question respecting the stability of the Rokugo-*gawa* Bridge, which was the first large bridge built in Japan. It was put up in 1875, a time when the rolling stock was somewhat lighter than that now in use. Oddly enough, the vibrations and deflections of this same bridge, and also others, were investigated in 1895 with apparatus similar to that now employed, and had Dr. Ōmori known this, it is possible that he would have compared the apparent state of the bridge at that date with what it was found to be five years later.

An account of this earlier work, with reference to that of others, as, for example, the seismometric measurements made by Prof. J. A. Ewing on the new Tay Bridge, will be found in *Engineering*, January 24, 1896.

The mechanical time marker used to determine the speed at which the record-receiving surface was moved, which is a determination of great importance when estimating vibrational periodicities, is apparently very similar to a contrivance largely used in seismometry in 1882 (see *Trans.* Seis. Soc., vol. iv. p. 97, Fig. 8).

A point not touched upon is a comparison between values given to displacements as measured by seismographs and as determined by the direct methods employed by engineers. Previous investigators have done a little in this direction, but before the confidence of the practical man can be obtained it is clearly necessary that this work should be extended. The results which, however, have been arrived at respecting the strength and rigidity of various types of iron girders by this neglected method of investigation appear to be worthy of consideration by the builders of bridges. In the *Erdbebenwarte* of last year there are three notices of Dr. Omori's important and carefully conducted investigations, which are now followed by the advertisement of an instrument maker who is prepared to supply engineers with apparatus designed for this particular class of work. J. M.

REPORT ON UNIVERSITY COLLEGES.

A REPORT upon the work of university colleges has been issued as a Blue-book and contains much information as to the provision for higher education in various parts of the country. An annual grant of 25,000*l.* is made by the Government in aid of certain university colleges, and the character and quality of the work done, with special reference to the difference between work of an elementary character and that of a more advanced nature, is tested by occasional inspection.

A visit of inspection was held in 1896 by Mr. T. H. Warren and Prof. G. D. Liveing, and another was made last year by Dr. H. G. Woods and Dr. Alex. Hill. The colleges visited were:—University College, London, King's College, London, Bedford College for Women (University of London), the Owens College, Manchester, University College, Liverpool, Yorkshire College, Leeds, the University of Birmingham, University College, Bristol, Durham College of Science, Newcastle-on-Tyne, University College, Nottingham, Firth College, Sheffield, University College, Dundee, Reading College, the Royal Albert Memorial College, Exeter, and Hartley College, Southampton. As has already been announced, the Reading College and the Hartley College, Southampton, have only recently been added to the list of university colleges, of which there are now fifteen which participate in the Government grant.

The present report is almost entirely made up of descriptions of the buildings and laboratories of each of the colleges, main lists of work, organisation, and position of various departments of arts and sciences. Preceding this is a general statement by Drs. Wood and Hill, and following it a report by Mr. H. Higgs upon the financial position of the colleges. A few of the points touched upon by Drs. Wood and Hill are mentioned below.

Plan of Buildings.—Anyone who makes the round of the university colleges is certain to develop in his own mind an ideal scheme of college buildings. Our own observations have led us to the conclusion that it is a mistake for a college to invest a large portion of its capital in buildings which cannot readily be adapted and extended to meet changing needs. We could cite cases in which much money has been spent upon the material fabric of a laboratory, whereas the want of funds to provide an adequate modern equipment seriously reduces the effectiveness of its work. The demands of science are constantly changing. It is therefore desirable that funds should be so husbanded as to allow of the provision of new apparatus and appliances of all kinds as they are called for. In this connection we feel that it is not too much to say that we have seen no single college in which adequate funds were available for departmental expenditure. A few departments of particular colleges which have been housed and equipped by private munificence are notable exceptions, but in the large majority of cases the funds assigned to departmental libraries, apparatus, lecture illustrations, &c., are altogether insufficient.

Statistics of Progress.—The general result of our observations and inquiries is to show that very remarkable progress has been made by the university colleges during the last five years. The great, we might almost say immense, growth is proved by the following statistics:—(1) The total amount of the benefactions

received during the last five years by the twelve colleges which participate in the grant amounts to close upon one million sterling. (2) The total number of day students attending the colleges during the session ending in July, 1901, was 7825, as against 7186 attending during the session ending July, 1896. (3) The advance in the standard of work is more striking than the advance in numbers. This advance is best shown by the larger number of university degrees obtained by students. The aggregate figures for the two periods are as follows:—1891-6, 1437 degrees; 1896-1901, 2186 degrees.

Position of Teachers.—Nothing has impressed us more than the enormous amount of routine work which the majority of university colleges exact from their teachers. There are, it is true, several exceptions. In certain colleges and in particular departments in which the number of students is small, the professors and their assistants have a good deal of leisure, and are able to undertake literary and scientific work with the support, in some cases, of fairly satisfactory libraries and laboratory appliances. In the larger and more successful colleges and departments the pressure upon the time and thought of the teachers is unduly great. If the head of a department is to maintain a high standard of teaching and to ensure a creditable list of examination successes he has little leisure for private work, and especially is he obliged to be assiduous in his duties because the students of the university colleges belong, for the most part, to a social class which exacts the maximum return in results for the fees paid. As to the effect of too much work upon the teacher there is no room for doubt. It tends to sap his intellectual vitality by leaving him neither time nor energy to draw fresh inspiration from the study of the work of others or from his own investigations. A fresh and unharassed mind is, above all things, necessary for research.

There is another respect in which, as it appears to us, the colleges are not serving their own best interests by overworking their teachers. The stipends which they offer are, for the most part, distinctly moderate. The opportunities for continued study and research are, except in London, inferior to those which Oxford and Cambridge afford. It can hardly be expected, nor is it to be desired, that a man of real capacity should look upon an appointment at a provincial college as a settlement for life. Rather should he regard it as a stepping-stone to preferment. If the colleges were to realise that the smallness of the stipend which they offer would be more than compensated in the eyes of an ambitious man by larger opportunities of qualifying for preferment, they would attract to their service young men of the greatest promise. If the probability of the advancement of its professors and lecturers to more lucrative and important posts is kept in view and their duties so arranged as to allow them leisure to display their capacity for original work, the colleges may count upon a supply of young men of the greatest ability who will occupy their chairs for a certain number of years while waiting to be called to a wider sphere.

Research.—We have found it difficult to give any adequate idea of the amount of original research in science which has been carried out by the teachers and students of the several colleges during the quinquennium under review. The greater part of the research work carried out at provincial colleges is done by heads of departments, and we recognise that a summary of each professor's own work would have greatly increased the value of our report. For several reasons, however, we have not felt ourselves at liberty to attempt this. In the first place, the leisure and, therefore, the opportunities for research, which the professors enjoy vary immensely. In the majority of cases we should say that the professor's duties are far too arduous and incessant to allow him to do much work of this kind. In the second place, we find that certain professors hold that it is the duty of the head of a department to work through his students. To them he conveys his ideas and affords constant assistance in carrying them out. A teacher who adopts this point of view may publish nothing under his own name, although all the work which emanates from his laboratory is really inspired by him.

Students and Original Research.—With regard to the question of the desirability of encouraging students to undertake original investigations, we find that teachers hold diametrically opposed views. Some consider that to set a student to such work is to rob him of the opportunity which his student days afford of acquiring information. Others look upon experience in research as the best training which any student can receive. The amount of research work done by students depends, therefore, to a certain extent upon the position which professors take with regard to this question. It may also be noted that the effort and originality required to produce "a paper" in some subjects is very different from that required in others. Probably the scope for original work in science is greatest in chemistry and least in physiology. In chemistry, too, the making of new substances and the investigation of interactions is a training in the science to a much greater extent than is similar work in any biological subject.

University Colleges and Secondary Schools.—We find that the relations of the more important provincial colleges to the secondary schools of their districts have become distinctly closer in the last five years. Not merely do more pupils pass from the secondary schools to the colleges, but reciprocity of representation on the governing bodies of schools and colleges is becoming more frequent, and there has been a certain amount of inspection of secondary schools carried out by members of the staff of several of the colleges. Another significant fact is that there have been of late several instances of denominational colleges, especially training colleges for the Nonconformist ministry, settling near university colleges in order that their students may attend university courses in arts and science. These facts point to the increasing importance of university colleges as educational centres.

University Colleges and Technical Education.—In an ever-increasing degree the university colleges are serving to co-ordinate the various agencies for higher education into an effective whole. They serve to focus educational forces. Particularly is their integrating action noticeable on the technological side, and although their results in this direction are not the phases of their activity which we were commissioned to investigate, they are, in our opinion, so desirable that we venture to call attention to them. Technical institutes are growing up in all large towns. When they are not in direct connection with the university colleges, where such exist, there is inevitably a certain amount of rivalry, with consequent friction, overlapping and waste of energy. The scientific direction of technological studies is a matter of national importance. In the technical departments of a university college, technical education is lifted to a higher plane. The head of a technical department, who is also a member of a college staff, and in close touch with the heads of departments of pure science, takes a higher and wider view of his own work, and inspires a more scientific spirit in his pupils. Further than this, the more capable of his pupils have the opportunity of prosecuting the study of the pure sciences as far as their inclination or financial resources allow. Not infrequently they discover in themselves an aptitude for science which would never have been suspected had they not joined a technical department for the purpose of acquiring instruction which would enable them to earn a living. In departments which would at first sight appear to be the most distinctly technical, we found that researches were being prosecuted which were helping to solve questions of general interest to men of science, the results reaching far beyond the interest of the particular industry to which the department belonged. Every year the boundaries which separate pure science from applied science become more indistinct. The physicist, the chemist and biologist make discoveries which prove to be unexpectedly useful in their application, while the technologist, going farther and farther afield, undertakes researches, the applications of which he cannot foresee, in the hope that he may light upon results which commerce can turn to account.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE pass list of the D.Sc. examination of the University of London contains the following names:—Mixed mathematics, Louis N. G. Filon (Granville scholarship); experimental physics, G. J. Parks, W. Watson; chemistry, R. H. Aders, R. M. Caven, C. H. Desch, E. J. Russell, J. Wade, Martha Annie Whiteley; botany, F. E. Weiss; zoology, H. S. Harrison (Sherbrooke scholarship), H. H. Swinnerton; physiology, Florence Buchanan, F. G. Hopkins; geology, C. A. Matley, E. W. Skeats.

THE Annual Calendar of the McGill College and University, Montreal, for the session 1902-1903 is a volume of more than four hundred pages filled with details of the buildings and equipment of the various departments, and the courses of work

carried on in them. The three buildings endowed and equipped by Sir William C. Macdonald for engineering, chemistry and mining, and physics, afford excellent facilities for study and research. There are special laboratories and workshops in which machinery of full size has been erected, so that all investigations can be carried on in all respects under working conditions.

THE tenth report of the Technical Instruction Committee of the County Borough of Plymouth has been received. The concluding words of the report show that the committee realises that fundamental principles rather than technical details should be the object of the work in such municipal science, art and technical schools as that at Plymouth. The committee remarks :—"It must not be assumed that the work of the schools is intended to embrace what are commonly called technical subjects only. Their object is to give such higher education and training, combined with manual and technical skill, as may enable their students to perform their work in life with greater intelligence, ability and success."

SINCE Prof. Perry brought forward the subject of "The Teaching of Mathematics" at the meeting of the British Association last September, several associations of teachers have discussed the reforms suggested or appointed committees to report upon the matter. A committee of the Assistant Masters' Association has had the subject under consideration, and a preliminary report has been drawn up, from which it appears that masters in secondary schools are in favour of most of the reforms advocated by speakers at the British Association meeting. The report is as follows :—I. *Arithmetic.* (1) The method of teaching in the early stages should be inductive and concrete. Actual measuring and weighing should be introduced as early as possible. (2) Decimals should be treated as an extension of the ordinary notation, their nature being illustrated by actual metric weights and measures. Multiplication and division of a decimal by a decimal would, we think, have to follow vulgar fractions. (3) The decimalisation of English money and English weights and measures should be practised frequently. (4) Approximate methods should be gradually introduced after the treatment of finite decimals. They should be taught with due regard to rigidity of proof. Appreciation of the degree of approximation should be continually insisted upon. (5) If "commercial arithmetic" is to be taught at all, the subject-matter should receive more adequate and correct treatment, and the examples should be drawn from transactions as they actually occur.—II. *Algebra.* (1) The foundation of algebra should be "literal arithmetic," *i.e.* algebra should at first be arithmetic generalised. (2) The minus sign should receive its extended meaning from copious illustrations; and illustrations, not rigid proof, should also be resorted to for the purpose of the "rule of signs." (3) Algebra should often be applied to geometry. (4) Logarithms should form an important section of the subject. We believe that the graphic method could be very usefully employed in this connection. (5) We desire to deprecate the waste of time so commonly practised in mere manipulation of symbols.—III. *Geometry.* (1) We are strongly of opinion that the ordinary deductive geometry should be preceded and continually supplemented by concrete and inductive work. (2) Whilst "mensuration" might possibly be taught in connection with physics and arithmetic, we believe that the value of geometry would be enhanced by practical applications of the propositions as they occur. (3) We feel very strongly that Euclid's text is very unsuitable for teaching geometry. But we are impressed with the difficulty of abolishing its use in the face of external examinations. In the circumstances, we can only hope that examining bodies, even if they insist on Euclid's sequence, will allow greater latitude in methods of proof, and give greater prominence to easy "riders" and applications of geometry.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 12.—"The Dissipation of Energy by Electric Currents induced in an Iron Cylinder when rotated in a Magnetic Field." By Ernest Wilson, Professor of Electrical Engineering, King's College, London.

The effect which induced currents have upon the distribution of magnetism in an iron cylinder, when rotated about its longitudinal axis with uniform angular velocity in a magnetic field, has already formed the subject of a communication (Wilson, Roy. Soc. *Proc.*, vol. lxix. p. 435, also NATURE, vol. lxv. p. 502). The present paper deals with the energy dissipated by these electric currents, and a comparison is made between the results of experiment and theory. In connection with the theory of the subject a contribution by Mr. J. B. Dale is made use of. The cylinder experimented upon has diameter and length each 10 inches (25·4 cm.), and is rotated between the poles of a magnet weighing some tons. It is supplied with exploring coils, threaded through holes drilled in a plane containing its longitudinal axis, by the aid of which the electromotive forces due to rotation in a magnetic field have been observed. The results of experiment have been obtained graphically by a process of double integration. The distribution which has to be assumed in connection with the experiments is that the induced currents distribute themselves on the surfaces of cylinders similar to and concentric with the cylinder experimented upon. Two other distributions are also discussed, namely, the distribution assumed by Baily (*Phil. Trans.* Roy. Soc., A, vol. clxxxvii., 1896, pp. 715–746), that in any section the electric currents flow in rectangular paths similar to the boundary of the section, and the distribution in which the current density in any path is constant throughout the path.

Dealing with the distribution assumed in connection with the experiments, both graphical treatment and theory agree in giving the formula $3{\cdot}95B^2f^2l^2/10^{16}\rho$ for the watts dissipated per cubic centimetre, where B is the intensity of magnetic induction assumed constant, f is the frequency, l is the length of the cylinder assumed equal to its diameter, and ρ is its specific resistance. In the experiments the frequency was varied from 1/45 to 1/360, and for each the average intensity of induction was varied from 1000 to 20,000. In each case the watts per cubic centimetre are less than would be dictated by the above formula. The ratio of the results is 1·3 at frequency 1/360, and is substantially constant for all values of the induction density. At frequency 1/45 this ratio varies from 1·4 to 1·7 for high and low values of the induction density, but it is 3·1 for an intermediate value. A similar, though less marked, effect is observed at frequency 1/90. The explanation given is that with these intermediate forces at these frequencies very great crowding of the induction to the surface occurs; and, moreover, since the wave-form of the electromotive force near the surface of the cylinder in all the experiments is more rectangular, the dissipation of energy per cubic centimetre is less than the formula above would give, since *there* the wave-form is assumed to be a sine-curve. On the assumption that the electromotive force at the surface is truly rectangular, the formula obtained by graphical treatment is $2{\cdot}0SB^2f^2l^2/10^{16}\rho$.

Having reconciled the results of experiment with those of theory, the author compares the dissipation of energy in rotating and alternating magnetic fields. It is pointed out that in the case of circular plates in which the diameter is very great as compared with the thickness, and in which the lines of force are uniformly distributed in the plane of the plate, the rotating field would dissipate about 1·7 times as much energy as an alternating magnetic field in the same time. The results are, however, greatly influenced by variation in wave-form, and even when the lines of force are confined to the plane of the plate, a condition not always met with in practice, the rate of dissipation of energy for a given average induction density may be considerably reduced if the distribution of magnetic induction is such as to give a more rectangular wave-form to the induced electromotive force.

"Note on a Magnetic Detector of Electric Waves, which can be Employed as a Receiver for Space Telegraphy." By G. Marconi, M.I.E.E. Communicated by Dr. J. A. Fleming, F.R.S.

The detector is based, in the author's opinion, on the decrease of magnetic hysteresis which takes place in iron when, under certain conditions, it is exposed to the effects of Hertzian waves. On a core of thin iron wires is wound a coil consisting of one or two layers of insulated copper wire, and over this and separated from it by insulating material is wound a second longer coil. The ends of the inner coil are connected to earth and the aerial conductor, and the ends of the outer coil to a telephone. The iron core is magnetised by a permanent magnet at one end, which is rotated by clockwork so as to cause a continual slow change in the magnetisation. The magnetisation, however, lags behind the magnetic force owing to the hysteresis of the iron, but when a high-frequency current passes through the inner winding there is a decrease in the hysteresis, due

apparently to the iron molecules being momentarily released from constraint. A sudden variation in the magnetisation of the iron results, and this induces a current in the outer copper winding connected to the telephone. The author finds that the telephone reproduces very accurately the transmitted signals, and that the receiver is more sensitive than the coherer and more suitable for use with a syntonic system of wireless telegraphy. Experiments with the receiver have been carried out between St. Catherine's Point and North Haven, the distance between these points being 152 miles; the length of the electric waves used was 200 metres.

"A Note on the Effect of Daylight upon the Propagation of Electromagnetic Impulses over Long distances." By G. Marconi, M.I.E.E. Communicated by Dr. J. A. Fleming, F.R.S.

During the experiments carried on between Poldhu, Cornwall, and the U.S. s.s. *Philadelphia* it was observed that the signals transmitted at night had a greater carrying power than those transmitted by day. The transmitting conductor consisted of fifty bare copper wires suspended from a wire stretching between two poles 48 metres high. On board ship the receiving conductor was suspended from the mast and was composed of four wires the tops of which were 60 metres above the sea level. Signals were sent from Poldhu at stated intervals from 12 to 1 a.m., from 6 to 7 a.m., from 12 to 1 p.m. and from 6 to 7 p.m. Until the *Philadelphia* was 500 miles from Poldhu no differences were observed; at distances of more than 700 miles signals transmitted during the day failed entirely, whereas those sent at night remained quite strong up to 1551 miles and were decipherable up to 2099 miles. Daylight at Poldhu was rapidly increasing from 6 to 7 a.m., and it was observed that on the *Philadelphia* the signals which were quite clear at 6 a.m. had almost disappeared by 7 a.m. Confirmatory tests were carried out between Poldhu and North Haven, and it was found that receiving wires 12·1 metres high could be used at night, but that, other things being equal, the height had to be increased to 18·5 metres for the daylight signals to be equally clear. The author suggests that the effect may be due to the diselectrification of the transmitting elevated conductor by daylight, the electrical oscillations being thereby prevented from acquiring so great an amplitude as they attain during darkness. That the effect has not been previously noticed may be due to the extra high potential to which the aërial wires at Poldhu were charged for this long-distance work. This potential was sufficient to cause sparking between the tops of the wires and an earthed conductor 30 cm. distant.

EDINBURGH.

Royal Society, June 16.—The Hon. Lord M'Laren in the chair.—Prof. C. G. Knott read a paper on the change of resistance of nickel due to magnetisation at various temperatures. The apparatus used had been constructed twelve years ago in Japan, but other work had prevented anything like a thorough investigation being made with it. Two exactly equal pieces of nickel wire were coiled so as to form anchor-ring cores to magnetising coils of copper wire coiled round them. Round each nickel wire were coiled two distinct coils with exactly the same number of turns. Thus by joining up the coils in different ways the experimenter was able to subject the enclosed nickel to a strong magnetic field or to no field, without in any way altering the strength of current circulating in the coils. The nickel coils were balanced on a Wheatstone bridge. The magnetising current was passed round the pairs of coils on the nickel cores, so as to magnetise the one nickel but not the other. In this way the heating effect was practically the same in both coils and the change of resistance due to heating very nearly compensated. The coils were heated up to various temperatures in an air bath and the resistance change was measured by deflection after a balance was nearly adjusted. The galvanometer was gauged by means of the deflection produced when a definite change of resistance was made in one arm of the bridge. The first series of experiments indicated that there was a decrease in the proportional change at higher temperatures; but this showed that the total amount of change estimated in ohms for any given wire was very nearly the same at all temperatures between the limits of 10° and 170° C. The bearing of this result upon Prof. J. J. Thomson's theory of corpuscles was pointed out; but further results were held over for another communication.—Prof. Knott also gave an account of the last piece of quaternion work which Prof. Tait had jotted down on July 2, 1901, just two days before his death. The notes bore upon the properties of the linear vector function and were a following up of previous work published in the *Proceedings*.—Dr. Hugh Marshall described the results obtained by him in the first part of an investigation of the thallic sulphates and double sulphates. From these it would appear that it is largely a matter of solubility whether normal or basic salts are obtained, rather than a matter of sulphuric acid concentration. Thus, potassium thallic sulphate, $KTl(SO_4)_2,4H_2O$, when treated with dilute sulphuric acid gives a sparingly soluble basic salt, $K_2TlOH(SO_4)_2$; the latter dissolves easily in dilute nitric acid and this solution gives crystals of the first-mentioned normal salt. No thallic alums could be obtained.

July 7.—Sir William Turner in the chair.—An obituary notice of Lieut.-Colonel J. H. B. Hallen, C.I.E., F.R.C.S.E., was communicated by Principal W. Owen Williams.—Mr. J. G. Goodchild contributed a paper on Scottish mineralogy, based upon a study of the specimens under his charge in the Edinburgh Museum of Science and Art. It dealt chiefly with the developmental history of albite studied in relation to crystal genesis in general. The paper also dealt with the crystallography of Scottish cerussite, analcine, forsterite and some others. Drawings of a large number of crystals were exhibited.—Mr. James N. Miller demonstrated the mode of applying his mechanical trisector to the quinquesection of an angle. It was an ingenious extension of the properties of the trisector.—In a paper on experimental observations on leucolysis, by Drs. A. Goodal and E. Ewart, the following conclusions were arrived at:—(1) Necrobiotic changes occur in the circulatory leucocytes in health; (2) these changes are much more evident in conditions of impaired nutrition and toxæmia, notably in cancerous cachexia; (3) in toxic conditions usually associated with leucocytosis the extent of the necrobiotic changes in the white cells varies in inverse ratio to the number of leucocytes in the circulating blood; (4) these necrobiotic changes can be rapidly induced "in vitro" by the action of certain organisms or other products; (5) the rapidity and extent of the changes depend on the kind of organisms, the virulence of the culture and the number of organisms employed.—In a paper on cross-magnetisation in iron, Mr. James Russell described a large number of experiments showing how the induction, either longitudinal or circular, was affected by cross fields and how the effects of these cross fields were themselves reacted upon. As one among many results, consider the case of a steady longitudinal field with a cyclically changing circular field superposed. The induction due to the longitudinal field went through a corresponding cycle with its maximum points occurring at the instants of greatest change in the cyclic circular field. The cyclic change in the longitudinal field was very similar in form to the change accompanying twisting.—In a note on a suggested improved method of measuring deep-sea temperatures, Prof. Knott called attention to the unsatisfactory character of the methods at present in use, and advocated the use of the platinum thermometer, with which the temperature must be taken *in situ*. Various obvious difficulties in the way of applying the platinum thermometer to deep-sea work were considered, also the manner of measuring the depth at the instant of taking the reading. For experiments down to moderate depths there was no special difficulty in using these electric resistance thermometers, and by such rapidly acting apparatus important problems connected with the penetration of solar radiation through surface waters could be readily solved.

PARIS.

Academy of Sciences, July 24.—M. Bouquet de la Grye in the chair.—On electrolytic actions developed by batteries consisting of two liquids, one being an acid, the other an alkali, by M. Berthelot.—On the existence in the albumin of birds' eggs of a fibrogen substance capable of being transformed, *in vitro*, into pseudo-organised membranes, by M. Armand Gautier. Fresh white of egg, after filtration through paper, was diluted with water and treated with a current of an indifferent gas, such as nitrogen or carbon dioxide. A substance is precipitated in the form of white transparent membranes, possessing a rudimentary organisation, and approximating in composition to the fibrin of human blood and to myosin, but differing considerably from egg-albumin.—On the glycuronic acid in the blood of the dog, by MM. Lépine and Boulud.—Report on a memoir of M. Torres concerning a scheme for a steerable balloon presented to the Academy on May 26. The committee regards the work of M. Torres as constituting a very interesting contribution to the theory of steerable balloons, and considers it desirable that

experiments on the subject should be made.—The mission to Martinique; extract from a letter of M. Lacroix to M. Michel Lévy. A short account of the experiences of the exploring party. Stress is laid on the fact that no heavy masses appear to have fallen upon St. Pierre; the destruction must have therefore been due to the effects of masses of incandescent gases. The torrential rains have caused great ravages, and in some cases have changed the hydrography of the coast. Soundings show that the sea bottom near the coast line has not undergone any appreciable alteration.—On the generalisation of the analytical prolongation, by M. Émile Borel.—Observations on the preceding communication, by M. P. Painlevé.—Anomalies presented by the charge of isolated conductors on solid dielectrics. Particular magnetic phenomena proved in the neighbourhood of the nodes of electric oscillations, by M. V. Crémieu.—On the mechanical phenomena of the electric discharge, by M. Jules Semenov. It has been generally supposed that when a spark passes between two conductors material particles are torn off each pole and carried to the opposite pole. The author describes experiments which show that no particles are removed from the positive pole and that the material carried by the spark towards the negative pole arises exclusively from the gas or vapour in the immediate neighbourhood of the positive pole.—Photograph of a multiple lightning flash, by M. Piltschnikoff.—On magnetic double refraction, by M. Quirino Majorana. The study of magnetic double refraction in solutions of ferrous chloride and of dialysed ferric oxide has led to the deduction of the following laws: the double refraction is proportional to the thickness of the liquid normal to the lines of force, to the concentration of the liquid, to the square of the field strength and to the reciprocal of the square of the wavelength.—On the atomic weight of radium, by Mme. Curie. By concentrating by fractional crystallisation a large quantity of radiferous barium chloride, about 0·1 gram of radium chloride has been obtained, the atomic weight of which, on the assumption that radium is a divalent metal, is 225. According to its chemical properties radium belongs to the series of the alkaline earths. The anhydrous chloride is spontaneously luminous.—The action of hydrochloric acid upon the sulphates of aluminium, chromium and iron, by M. A. Recoura. By the action of hydrochloric acid upon chromium sulphate a chromium chlorosulphate is obtained, $CrSO_4Cl,6H_2O$, the chlorine of which is not precipitated from its aqueous solution by silver nitrate. Freezing-point determinations showed that this compound is not dissociated in aqueous solution.—On the mixtures formed by sulphur and phosphorus at temperatures below 100° C., by M. R. Boulouch. No definite chemical combination of sulphur and phosphorus appears to be formed below 100° C. A eutectic mixture which melts sharply at 9°·8 simulates a definite compound.—On the precipitation of copper bromide and chloride by sulphuric acid, by M. Georges Viard.—Study of cerium silicide, by M. Sterba. A well-defined crystallised silicide of cerium is obtained by heating together cerium oxide and silicon in the electric furnace. Its composition is $CeSi_2$, and it possesses great stability. Its properties are different from those of calcium silicide and approximate rather to those of the silicides of the heavy metals.—The action of alcohols upon the sodium derivatives of other alcohols, by M. Marcel Guerbet. A mixture of œnanthyl alcohol, ethyl alcohol and sodium heated in sealed tubes to 230° C. gives some normal nonyl alcohol. The method appears to be a general one for obtaining higher homologues of the higher alcohols.—Study of the simultaneous distillation of two non-miscible substances, by MM. Eug. Charabot and J. Rocherolles. The ratio between the weight of a substance not miscible with water and the weight of water which distils simultaneously varies in the direction approaching unity when the temperature increases short of the critical temperature of one of the liquids.—On a new di-iodophenol, by M. P. Brenans.—The action of nitrous acid in acid solution on the α-substituted β-ketonic esters; the synthesis of homologues of pyruvic acid, by MM. L. Bouveault and R. Locquin.—On a method permitting of the separation from complex animal or vegetable liquids of the greater part of the ternary substances and several of the bases which may accompany them, by M. S. Dombrowski.—The variations of the iodine in the blood, by MM. E. Gley and P. Bourcet.—The pharmacodynamic properties of some aromatic semicarbazides, by MM. Auguste Lumière, Louis Lumière and J. Chevrottier.—The experimental transmission to descendants of lesions developed in the ancestors, by MM. A. Charrin, A. Delamare and Moussu.—On the evolution of the cranial ring detached by trepanning and immediately transplanted, by MM. V. Cornil and Paul Coudray.—Mosquitoes and yellow fever in Havana, by M. André Poey.—The elaboration of zymogen in the gastric glands of the snake Berus, by M. L. Launoy.—On artificial parthenogenesis, by M. C. Viguier.—The production of sleep and local and general anæsthesia by electric currents, by M. Stéphane Leduc. With electric currents the complete inhibition of the cerebral centres can be instantly obtained and without apparent pain, leaving intact the centres of respiration and circulation. A complete general anæsthesia can thus be obtained which is without any after action.—Spermatogenesis in *Cybister Roeselii*, by M. D. N. Voinov.—On the *rôle* of the spleen in the hæmatolytic function, by M. Louis Lapique.—On the presence of lecithin in plants, by MM. Schlagdenhauffen and Reeb.—On the conservation of the germinating power in seeds, by M. L. Maquenne.—On the specialisation of parasitism in *Erysiphe graminis*, by M. Ém. Marchal.—On the hydrography of Tidikelt in the Central Sahara, by M. G. B. M. Flamand.—On the constitution of the sea floor, by M. J. Thoulet.

THURSDAY, AUGUST 7, 1902.

HANN'S METEOROLOGIE.

Lehrbuch der Meteorologie. Von Dr. Julius Hann, Professor an der Universität in Wien. Mit 111 abbildungen im text, 8 tafeln in lichtdruck und autotypie, sowie 15 karten. (Leipzig: Chr. Herm. Tauchnitz, 1901.)

THIS remarkable book had its origin in a suggestion by the publishers that Dr. Hann should write a text-book of meteorology for students. As the author himself points out, it has travelled far beyond its original object, and as it stands it constitutes substantial ground for increased gratitude to Dr. Hann from meteorologists of all countries, by whom he has long been recognised as a master in the subject. The book is a veritable encyclopædia of meteorological science. It consists of 792 pages of text, and each page is made up of small type, smaller type and smallest type. The small type gives the professor's current narrative; the smaller type gives a large number of technical details; the smallest type embodies a most valuable series of references with critical notes; and the whole constitutes a complete representation of the present position of meteorological science apart from those climatological details which are given in Dr. Hann's well-known "Climatologie."

The arrangement of the book is on physical lines. After a general introduction, temperature in all its relations, pressure, moisture, wind phenomena and dynamical meteorology, *i.e.* the meteorology of atmospheric disturbances, are successively treated, while an appendix gives some of the most important of the mathematico-physical theories of meteorology.

One striking feature which illustrates the wide range of the book is the number of distinguished physicists and chemists whose researches have contributed to the development of meteorological science and whose papers are quoted or referred to. Among English physicists the names of J. W. Strutt, Lord Rayleigh, Lord Kelvin, Stokes, Osborne Reynolds, Shelford Bidwell, W. Ramsay, J. J. Thomson, Abney, Schuster, Oliver Lodge, Poynting, all appear as responsible for various meteorological contributions, and a similar list of names might be adduced for other countries. It may surprise physicists generally to learn how many of their distinguished colleagues are referred to in a work which deals with the present state of meteorology adequately. It is satisfactory evidence that meteorology has not yet drifted out of touch with modern physics.

The arrangement is so skilful that every page of the book is full of interest. It takes a thoroughly rational and impartial view of all meteorological theories and speculations, gives an account of the results derived from the discussion of most voluminous meteorological observations, and in spite of the huge mass of material with which it deals it manages to keep the reader's attention. It is, indeed, difficult to read because it is so full of matter and so skilfully arranged that the reader is hardly willing to regard one page as exhausted and to go on to the next. The illustrations are all most carefully selected, excellently reproduced, and some of them are impressive examples of the possibilities of photographic reproduction in what may be called the department of the natural history of the atmosphere. They make one wonder whether it is not really an advantage for other departments of natural history and for the public that their specimens are so unwieldy that they must be broadly displayed in a suitable museum instead of being neatly folded away in books and stored on the upper floors of an office. No doubt Dr. Hann, who for so many years has been in touch with meteorologists of all countries, is in a position of special advantage in regard to the work of compiling such a book, but when all his advantages are taken into account the reader cannot help being amazed at the skill and judgment with which the organisation of the facts has been carried out. Whether one deals with the variation of meteorological elements from hour to hour, from day to day, from month to month or from year to year, the statistical results are so clearly and concisely expressed and the salient features so well marked by special type or other devices that the reader can draw his own conclusions with ease. To take a trivial example, on p. 335 we find statistics of the diurnal distribution of rain. Those who are interested in such matters may see at a glance that at Kew in summer the most unfavourable hours for a garden party are from 2 to 4 in the afternoon, and next to those from 4 to 6, when the frequency of rain is about half as much again as it is between 6 and 8 a.m., whereas in winter from 4 to 6 is the best time of the day from the point of view indicated. On the other hand, at Valencia the frequency of rain from 4 to 6 in the afternoon in summer is not much more than half the frequency at the corresponding morning hours.

The work is brought very closely up to date. The most recent developments of the study of the upper atmosphere by means of kites, balloons and clouds are noted, and some of the results of the simultaneous balloon ascents under the auspices of the International Aëronautical Committee are included.

In dealing with the physical aspects of meteorology the author exhibits the same comprehensive grasp of the subject and the same conciseness of style as when dealing with the direct results of observation, but here the reader may find himself at fault. The science requires a knowledge, not only of meteorological facts, but of the physical and chemical theory which is necessary for the appropriate coordination of the facts. The author briefly incorporates all contributions to the science, and naturally when he makes use of physics or chemistry or mathematics he does not stay to develop the necessary introductory study of those sciences. The consequence is that many concise and comprehensive sentences require a considerable amount of antecedent knowledge for their full appreciation. As an example of the rapidity with which subjects are passed under review, I quote the paragraph which deals with the selection of the thermometric scale, as follows:—

"Die Fahrenheitsskala ist noch in allen Ländern englischer Zunge, selbst in wissenschaftlichen Werken üblich. Als ein Vorteil derselben wird angeführt dass man weniger mit negativen Graden zu rechnen hat und dass der Grad kleiner ist, weshalb es vielfach genügt die Temperatur nur in ganzen Graden anzugeben,"

with the footnote,

"Sehr auffallend muss es erscheinen dass die namentlich für physikalische Formeln ganz unbehilfliche Fahrenheitsche Skala noch jetzt bei Männern der Wissenschaft Verteidiger findet. M. S. z. B." Buchanan, in NATURE, August 17, 1899. "Auch Sir John Murray ist für die Fahrenheitsche Skala."

The words are few, but they give a remarkably vivid picture of the present position of a very important question, and the example is quite typical of the author's style.

When an author with this power of concise representation deals with the present state of our knowledge of the composition of the atmosphere, solar radiation and its measurement, the general circulation of the atmosphere, the thermodynamics of the atmosphere and the modern developments of atmospheric electricity, it will be evident that he has gone far beyond the limitations of an introductory text-book and addresses himself to mature students.

In order to deal more completely with the theoretical side of the subject, an appendix of sixty-eight pages is devoted to the exposition of some of the most important mathematico-physical theories of meteorology and their applications. In this are included (1) the calculus of periodic phenomena; (2) the distribution of heat in the ground; (3) thermal distribution in the atmosphere; (4) nocturnal changes of temperature and the coefficient of radiation of atmospheric air; (5) the vertical distribution of pressure and its relation to temperature and moisture; (6) measurement of height by the barometer. These involve an adequate knowledge of mathematical processes and may be found difficult by those who are not familiar with mathematical physics.

For this reason the book must be regarded as encyclopædic rather than didactic. The beginner who reads it will be conscious that he has much to learn, and even the expert will realise that there are many things he would like to pursue further. Yet the style is happily chosen. It will be recognised that means of obtaining the necessary information are everywhere available for students who desire it, and to have amplified the work by including instruction in the indispensable preliminary knowledge would have spoilt it. Dr. Hann is entitled to the sincerest congratulations on the rapid completion of so thoroughly comprehensive a treatise. There can be no question that the publication of so complete a summary of meteorological knowledge must lead to important developments from the many points of scientific and practical interest which are exhibited. It is indeed fortunate for the science that the University of Vienna is able to afford to so distinguished a meteorologist opportunity for the prosecution of this important work.

W. N. SHAW.

THE FIBRE INDUSTRIES.

The Textile Fibres of Commerce. By William S. Hannan. Pp. x + 236. (London: Charles Griffin and Co., Ltd., 1902.) Price 9*s.* net.

THE title of this work raised a hope that the author had seized the opportunity open to any specialist of carrying on the critical labours of Vetillart, Wiesnet, Hugo Müller, J. Christie, Otto Witt, and the experts of the Colonial and Indian Exhibition, now almost of ancient history. The opportunity is a great one; for the subject-matter is vast, the interests involved are stupendous, while the first principles of the subject are few, very few, and so are they who recognise them. The opportunity is one, not merely for a book enunciating in one comprehensive view the relationships of our highly developed textile methods to one another and to the properties of the ultimate spinning units, but for a definite forecast of the progressive future, which is of obvious commercial moment.

The book before us, however, neither aims at nor claims to reach the pioneer standard of technical literature, and must be judged accordingly. The author's labours have no doubt been exhaustive and minute. But the failure to attain to the ideal standard is self-predicted by the opening sentence of the introduction:—

"The vegetable and mineral fibres of commerce may be arranged in four groups, viz. (1) plumose fibres; (2) stem and leaf fibres; (3) fruit fibres (all derived from plants); and (4) mineral fibres. These groups are represented by the fibres used in various important industries, and by other vegetable fibres which at present are of special interest from a scientific point of view only."

This classification has no morphological basis and is devoid of technical significance. The sentence stands immediately beneath the title "The Textile Fibres of Commerce," and the reference to these "other fibres," which are, in fact, from the point of view of commerce or industry, mere lumber, introduces us to the supposed antithesis of science to commerce, which is archaic, but in these days misleading, and were better left out. The introduction, in short, prepares us for the plan actually followed in the book, which is that of alphabetical sequence of the conventional or trivial names of the fibres; perhaps the best in the absence of a positive, critical basis and consequent classification. The reader is thus prepared to find the book a non-critical compilation, and although the title suggests the subordination of the matter to commercial, that is industrial,proportions, the expert will be disappointed and the lay reader will get little instruction in the *practical science* of the subject.

Of course, be it understood, a book of 230 pages, upon such a subject, and containing 150 illustrations, mostly the original work of the author and friends, affords much interesting reading. This interest belongs to the subject, which is fascinating from whatever point of view it may be handled. We have no wish to depreciate the author's evident aim to popularise the subject; on the contrary, we wish for the book a successful run, and that a second edition may see a considerable improvement in the matter. But as we take the request in the preface for "any suggestions that will enable me to add to the utility of this work" as an honest invitation to the critic, we feel we should be wanting in honesty and in a duty to the technical public if we shirked the task of pointing out by a few examples the author's want of precision in handling fundamental questions. We cite first the introductory sentence of the section "Vegetable Fibres," p. 3, "Physical and Chemical Properties," which reads, "The principal vegetable fibres are plumose and

bast. Both are used for spinning and weaving, and their prices fluctuate in accordance with the quality and quantity of the annual crops. The plumose fibres are composed of cellulose."

Plumose and bast should not be coupled with the same term "fibre" unless the author intends "ultimate fibre." We take it that the spinning unit is intended, and in the case of the bast fibres the unit is a more or less complex *filament*. Fibres are not used for spinning *and* weaving; the fibres or filaments are spun into yarns and the yarns woven. It is fairly obvious that prices vary with supply and quality, but there is something to be said for demand. Why, however, interject this superficial reference to the important question of value under the heading of "Physical and Chemical Properties"?

Lastly, to describe the plumose fibres as "composed of cellulose" is misleading. In the cotton substance the non-cellulose, it is true, is small in proportion, but the composition of the *eriodendron floss*, as of other seed hairs, is widely divergent.

Later in the section we find the bast fibres described as made up of cells of which the "walls are composed of more or less thickened lignin or woody material." This is quite inaccurate in regard to the most important of them, viz. flax, hemp and rhea.

Again, the "good commercial qualities" of the fibro-vascular bundles of monocotyledons "depends upon their moderate length, strength, flexibility, and the number of fibre cells in each bundle." Without reference to the grammatical slip, we will fix the looseness of the phraseology by transposing the terms to another case. "The good commercial qualities of gold depend upon its moderately yellow colour, specific gravity, ductility, and the number of silver coins of equivalent value"!

We have dealt with this section on "Physical and Chemical Properties" at disproportionate length, for the author exhausts it in a single page of matter. The failure to lay a solid critical foundation by an adequate treatment of the section, of obviously fundamental import, measures the failure of the work to contribute to the systematic development of the subject.

We are bound, further, to particularise some strange inaccuracies in the information conveyed to the perhaps unsuspecting reader. Jute is described under the heading "Jute, Common," and the description contains many curious statements. Thus:—

"The fibres are several feet in length, have a satiny lustre on account of which they are sometimes used in the manufacture of the cheaper silks."

There is a popular confusion, we presume, between jute and "jute"; there is also a slang word "water" well known "in the city," but we suggest that only in the official mind of a judge of the High Court would there be any possible confusion of the material with the immaterial "water." So we venture to think that the author has served up a popular error in relation to "jute" as an industrial fact in relation to jute.

In particularising the applications of jute yarns we find,

"the backing of hearthrugs, the lining of ladies' slippers, the collars of gentlemen's coats and burlaps for bales of jute or hemp coverings."

We refer the author to Dundee for information.

Lastly, "the jute fibre readily dissolves in alkalies and mineral acids at a low temperature." The reader may correct this statement by reference to any of the standard works on cellulose chemistry.

The chemistry of the fibre substances is dealt with generally in a superficial way. The author should have been careful to avoid such statements as the following in reference to cotton (p. 91):—

"Acids have so destructive an effect upon cotton that their use in the cotton industry ought generally to be dispensed with, since alkalies such as soap . . . can be employed for scouring and cleaning cotton fibres without materially injuring them."

And again (p. 97),

"Cotton fibres have some affinity for vegetable dye stuffs such as indigo . . . but little or none for coal-tar dyes."

The section on "Cotton" otherwise contains useful information of a conventional commercial order, and as it comprises some forty-five pages is clearly the most important of the book. In the categorical description of the various cottons, the dimensions are given in inches and fractions of an inch. This in a scientific text-book is a gratuitous concession to the rigid conservatism of our industrial system. We should like to ask if the expression 1/1180 inch conveys any definite mental impression to the reader?

We briefly notice the section "Paper Fibre Plants." We all know that paper can be made from an endless variety of fibrous materials, and the author is evidently more impressed with the fact than with the advantage of using the qualifying term "commercial" as a winnow for separating the grain from the chaff. The paper-maker will find the section of little practical importance. The subsection "Woodpulp" opens with the curious sentence, "This is rather confused and mixed up with paper-making." The remainder of the section may be similarly described.

A subsection on "Woodpulp Silk" is rather out of place at the conclusion of the section on "Silk." The treatment of this highly important industry indicates that it lies outside the author's range of experience and does not invite serious criticism.

The author is entitled to the credit of having produced an interesting book on a universally attractive subject. That it does not take the place of a standard text-book of critical importance is due to the fact that he has not sufficiently grasped the trend of the progressive scientific movement which underlies the many-sided "commercial" developments of the fibre industries.

THE FISHES OF THE CONGO BASIN.

Les Poissons du Bassin du Congo. Par G. A. Boulenger. Pp. lxii + 532. (Bruxelles: Publication de l'État Indépendant du Congo, 1901.)

IT is a striking proof of the high estimation in which science is held by the authorities of the Congo Free State that they have devoted so much expense to the publication of the beautiful volume now before us, and it is also fortunate for science that the material was placed in the hands of so highly competent an ichthyologist as

Mr. Boulenger. Already a lavishly illustrated quarto volume ("Annales du Musée du Congo") had been issued containing descriptions and figures, by the same author, of new genera and species of fishes recently discovered in the Congo, and now comes the present work, the twenty-five plates of which are "half-tone" reproductions of the lithographs illustrating the descriptions in the "Annales."

This is the first work dealing with a group of animals over the whole extent of the Congo Basin, *i.e.* including Lake Tanganyika. It commences with an introduction divided into six parts, namely, (1) general characters of the fresh-water fishes of Africa, (2) distribution of fishes in the Congo Basin, (3) fisheries and methods of capture, (4) methods of preservation and transport of fishes for scientific purposes, (5) terminology used in scientific descriptions of fishes, (6) list of previous writings specially dealing with the fishes of the Congo Basin.

A few years ago, about 90 species of fishes were known from the Congo Basin, but in the present work the list is swelled to no less than 320, 78 of which are confined to Lake Tanganyika. The families most abundantly represented are Mormyridæ, Characinidæ, Siluridæ and Cichlidæ, the name for the last-mentioned family being for good reasons adopted in place of the better-known "Chromidæ."

I am glad to see that, in spite of Cope's dictum, Mr. Boulenger still considers the Lampreys to be "fishes," as he divides the class into three subclasses—Cyclostomi, Chondropterygii and Teleostomi. Only the last is represented in the fish-fauna of the Congo Basin.

The Teleostomi include here the Crossopterygii, the Dipneusti (the usual name "Dipnoi" is rejected on account of its having been originally used to designate the Batrachia) and the Teleostei. Our author seems inclined to retain the "Ganoids" (= Acipenseroidei and Lepidosteoidei) as a distinct order, but as none of these inhabit the basin of the Congo, the question is not gone into in a detailed manner. As to the Crossopterygii, Mr. Boulenger admits only two primary divisions, the extinct Osteolepida and the modern Cladistia, represented in African rivers by the singular though well-known family Polypteridæ, of which five species of Polypterus, three being new additions, and one of Calamichthys are here chronicled. As regards the Dipneusti, in the course of some interesting remarks on vertebrate limb theories, the author adopts Dollo's view as to their probable derivation from the Crossopterygii, the corollary to which, as the present writer has also pointed out, is that the "archipterygial" form of limb must have been diphyletically realised, on the one hand, by the Pleuracanthid Selachii, and on the other by the Holoptychii and the lung-fishes. An interesting new species of Protopterus (*P. Dolloi*) is here described and figured.

Proceeding to the ordinary bony fishes or "Teleostei," we may note in the first suborder, that of the Malacopterygii, the extraordinary variety of form among the Mormyridæ, even within the limits of one genus, as in the case of *Mormyrops curtus* and *M. attenuatus* (plate iii). Sagemahl is followed in the association of the four families of Characinidæ, Cyprinidæ, Siluridæ and Gymnotidæ in one group or suborder of Ostariophysi, the essential characteristic of which is the presence of the Weberian ossicles, by which the swim bladder is brought into relation with the ear. The Cyprinodonts, of which the region produces four species all belonging to the genus Haplochilus, are included with the Esocidæ, Dalliidæ and Amblyopsidæ in a third suborder, that of the Haplomi. A fourth is formed by the Percesoces (the Müllerian "Pharyngognathi" being entirely abandoned), and which includes, not merely the Scomberesocidæ, but also the Ammodytidæ, Atherinidæ, Mugilidæ, Polynemidæ, Sphyrænidæ, Ophiocephalidæ and Anabantidæ. Coming now to the fifth suborder of Teleostei, that of the Acanthopterygii, we find that, with the exception of a few Serranidæ, Sciænidæ and Pristipomatidæ, it is entirely represented by twenty-four genera and eighty-seven species of one family, that of the Cichlidæ (= Chromidæ of Günther). This family, which was also included in the "Pharyngognathi" of the Müllerian system, is here considered as closely allied to the Perches, in spite of the fusion of the inferior pharyngeal bones. The diversity of genera of this family in Lake Tanganyika is worthy of notice. The volume finishes with a description of eleven species of Mastacembelus (suborder Opisthomi) and one of Tetrodon (suborder Plectognathi).

In conclusion, it may be said that the talented author is to be congratulated on the interesting work he has produced, and the zoological public in having, in so compact a form, a guide to a general knowledge of the fresh-water fish-fauna of so large a portion of the African continent, interspersed with many valuable remarks bearing on the subject from a morphological as well as systematic standpoint. R. H. T.

APPLIED MECHANICS.

The Roorkee Manual of Applied Mechanics, Stability of Structures, and the Graphic Determination of Lines of Resistance. Vol. ii. By Lieut.-Colonel J. H. C. Harrison, C.E., late Assistant Principal, Thomason Civil Engineering College, Roorkee. Pp. viii + 318 + 70. (Roorkee: Printed at Thomason Civil Engineering College Press.)

THIS "Manual of Applied Mechanics" is primarily intended for the use of students of the Thomason Civil Engineering College, Roorkee, North-West Provinces, India. It forms an extension of vol. i.; the latter was originally prepared by Lieut.-Colonel A. Cunningham, R.E., and was revised by the present author in 1895.

Vol. i. does not include important subjects such as the stability of block-work, the design of retaining walls, abutments, masonry arches, earthwork, foundations, &c. These omissions have been met by the issue of vol. ii. Moreover, the treatment in vol. i. is mainly analytical, whereas in vol. ii. graphical methods have been developed and largely employed; so that the two volumes together now form a very complete treatise on the principles of mechanics as applied to roofs, girders, bridges, foundations and allied structures.

In the first part of the volume under review the author describes the plotting of vector and link polygons for a general system of forces in one plane. Then, in reference to various types of structures, such as beams, cantilevers, block-work, suspension chains, and arches he develops

the properties of these polygons and shows how, by their use, the shearing and bending actions, lines of resistance, &c., due to given loads may be determined. The drawing of link polygons so as to lie within given loaded arch rings is explained, and applied to the determination of the so-called line of least resistance of a masonry arch. The deflections of beams are next considered, and the link polygon method is extended and applied to the plotting of the elastic curves of loaded beams, including continuous beams. The latter were treated in vol. i. by the aid of the theorem of three moments. The student has thus the advantage of a comparison of the two methods.

Nearly a fourth part of the text is thus occupied in establishing the fundamental properties of the link and vector polygons, and then the author, in the second part, which comprises the remainder of the work, and is divided into three sections, proceeds to the practical applications.

Section i. deals with the stability and design of tall chimneys, buttresses, and various forms of cranes.

In Section ii. the subject of earth pressure is very fully considered, and examples are given of the design of retaining walls to resist the pressure of earth, and of masonry dams for reservoirs.

"Structures that span an interval" is the heading to the concluding Section iii.; and here the author treats very fully of masonry arches, fixed and continuous girders, cantilever bridges, stiffened suspension bridges, hinged metal arches, &c.

In an appendix a partial reprint is given of a paper by Colonel A. Cunningham on well foundations, which should prove of special interest to students and engineers in India, where, in spanning many of the rivers, the foundations have to be laid in quicksand.

It seems an unfortunate omission that in so excellent a treatise no reference is made to the application of the strain-energy method and the principle of least work to calculations on the deflections and stresses in braced frames, structures with redundant members, arched ribs, &c.; but otherwise the treatment is quite up to date. As regards practical construction, information is given as to the design of many details; and some examples of complete designs are fully worked out, and illustrated by drawings, taken principally, by permission, from Colonels Wray and Seddon's "Instruction in Construction." There are numerous folding plates, facilitating reference and allowing the figures to be drawn to a large scale.

The treatise can be recommended as a useful book of reference for engineers in the pursuit of their profession. Students who master the details of both volumes should, in the subjects of which they treat, be well equipped for their duties of after life.

OUR BOOK SHELF.

Ordnance Survey of England and Wales. Scale 4 miles to 1 inch, or 1 : 253,440. Sheet iv. Price 1*s.* 6*d.*

THIS sheet is a specimen of the new quarter-inch map of the British Isles which is being issued by the Ordnance Survey at Southampton, and we have pleasure in recognising in it many marks of the vitality of the Survey and of its power of employing the most modern methods to meet new requirements. The old quarter-inch map of Ireland in four huge sheets was a masterpiece of engraving and of printing directly from the plate; the old quarter-inch map of Scotland was a somewhat hapless attempt to show rivers in blue on an outline very sketchily printed from transfers in black, while the old quarter-inch map of England was a clear outline with fine lettering but little detail, the antiquity of which was thrown into painful relief by the insertion of railways up to a modern date. The new quarter-inch map of Great Britain, now in course of publication, is up to date in all particulars, and beautiful as well as accurate. The sheets are of convenient size (24 in. × 16 in.), the edges graduated to single minutes of latitude and longitude, with the meridians and parallels for each 20′ drawn clearly across the map, thus greatly facilitating the plotting of any distribution which has been worked out on maps of a larger scale, an advantage which will appeal to every geographical worker. The names and general detail are printed in black, the size of the lettering nicely graduated to show relative importance, and the style of execution is worthy of the best traditions of the old one-inch map. Railways are shown in a strong black line, county boundaries in a distinct dotted line, and roads of three classes are distinguished, the first class having the usual indication as to fencing and being coloured solid brown. Rivers and other water surfaces are given in blue, and when the altitudes marked on in bold black figures are considered the surface would appear to be so fully occupied that nothing could be added. Here, however, the chief novelty and beauty of the map appears. The configuration of the country is shown by a hill shading so expressive and unobtrusive that it actually seems to make more room for the other features, by throwing each into its own proper place and fixing it there. The blue threads of the water-courses accentuate the valleys of the high moorlands, the roads and railways are fitted with a pictorial commentary explanatory of every curve; even the county boundaries, so arbitrary on common maps, are seen to be natural lines, now a main watershed, again a powerful river. Colonel Johnston deserves the utmost credit for his bold and successful experiment in expressing relief without the use of contours or of hachures by the half-tone photographic reproduction of washes of colour. The hill-work is printed in brown, with which the blue of the water and the black of the names and railways contrast equally, and even the green with which extensive woodlands are shown stands out well.

The technical production leaves nothing to be desired, and we confidently place this map before any other in the world on the same scale for beauty of finish, accuracy of execution and sound judgment in the selection of features and names. It will be invaluable for mapping the distribution of phenomena in many branches of science, and welcome also to the tourist and motorist.

A Manual of Elementary Practical Physics. By Julius Hortvet, B.S. Second edition. (Minneapolis: H. W. Wilson, 1902.)

"LIFE is not long enough to admit of a *rediscovery* of the fundamental laws of physics. Besides . . . some of the laws were not discovered through experiment at all, but, on the contrary, were obtained by pure reasoning and afterwards verified by experiment."

This quotation will show that the author is not an adherent of the out-and-out heuristic school. But while it is not expected that a pupil shall go through the necessarily slow process of acquiring *all* his knowledge by his own investigations, he is expected to think for himself while the chain of reasoning to be followed and the conclusions to be drawn are indicated by questions which the pupil has to answer. While in sympathy, in the main, with this method, we do not think that the questions are always very happily chosen. Thus after experiments on the bending of a lath and the stretching

of a spiral spring occur the following:—"What quantities included among the above results are stresses and what are strains? State the relation between the elongation of the spiral and the stretching force. Does it appear that the elasticity of the spiral is perfect? State the relation between the force of elasticity and the elongation; also the relation between the elasticity of the spiral and the stretching force. State the relation between the strain and the stress."

We like better the instruction given in regard to the performance of the selected experiments, much of which appears excellent and should prove very useful to the teacher. It is a school-book, and we therefore notice with pleasure an adequate paragraph on "significant figures" and another on the plotting of curves. The book, although a second edition, is by no means free from mistakes and obscurities, some of which will be briefly mentioned. The standard metre is not the one preserved in the Archives of Paris, but one of those at the International Bureau at Sèvres. In connection with the barometer, "The same rise in temperature has caused the metal scale and tube to expand so that the observed height is too small." The expansion of the tube does not matter. On p. 136 we find, "Heat is a physical quantity in the same sense that force is a quantity," while on p. 73 it is stated that "force is not in itself a physical entity." In the former, did the author mean "energy" instead of force? The signs in the formulæ for lenses on p. 185 are very confused. "It is important that the principal axis of the lens should lie parallel with the line joining the centres of object and image, and be as near to that line as possible" (p. 186). Page 193, explanatory of electric capacity, is bad; while in the same chapter the phrase "touch B to bring its charge to zero" occurs twice, when potential, not charge, is meant. Lines of magnetic force are said on p. 197 to form closed circuits through a magnet, although such a line has been defined as giving the direction in which a north pole would be urged.

Such statements as these will mislead a teacher who is not very clear himself, and work the usual havoc. But a good man will receive a large number of useful hints from the book, and to such we commend it.

A. W. P.

The Journal of the Iron and Steel Institute General Index. Vols. xxxvi.–lviii., 1890–1900. Edited by Bennett H. Brough, Secretary. Pp. 511. (London: E. and F. N. Spon, Ltd., 1902.)

IT is impossible to over-estimate the value of collective indexes to the transactions of scientific societies as an aid to research. The new general index to the twenty-three octavo volumes of the *Journal* of the Iron and Steel Institute published during the years 1890 to 1900 inclusive is of special value, inasmuch as it contains references, not only to the authors and subjects of papers contributed to the Institute, but also to those of papers relating to iron and steel and cognate subjects published in other journals at home and abroad of which abstracts have been printed by the Institute. These abstracts are systematically arranged and constitute a valuable feature of the Institute's *Journal*. They indicate the great amount of activity at present exhibited in research and investigation connected with iron and steel. In 1900 no less than 1507 papers dealing with iron and steel, written in various languages, were abstracted. The general index furnishes, therefore, a useful means of reference to the whole field of recent literature of iron and steel. The volume also contains an interesting introduction tracing the history of the development of the Institute. From its foundation in 1869 to the end of 1900 it had published 581 original memoirs, and its *Journal* had covered 29,105 pages, with 1124 plates. This introduction is illustrated by full-page portraits of the sixteen past presidents, the seventh Duke of Devonshire, Sir H. Bessemer, Sir Lowthian Bell, W. Menelaus, Sir W. Siemens, E. Williams, J. T. Smith, Sir B. Samuelson, Dr. Percy, D. Adamson, Sir J. Kitson, Sir F. A. Abel, E. Windsor Richards, Sir David Dale, E. P. Martin and Sir W. Roberts-Austen.

Zur Metaphysik des Tragischer. By L. Ziegler. Pp. ix + 104. (Leipzig: Dürr'schen Buchhandlung.) Price Mk. 1·60.

A PLEASANTLY written little pamphlet on the spirit of tragedy and its philosophical implications. Mr. Ziegler's main contention is that the object of tragedy is to exhibit the absolute domination of the whole personality of the tragic hero by a single impulse or purpose. The tragic catastrophe affords, as it were, an ocular demonstration of the "illogicality" or "guilt" of any finite purpose which sets itself up against the totality of the world-process. This thought is then affiliated by the writer to the central idea of von Hartmann's doctrine of the unconscious, the "redemption" of the "cosmos" from itself. As in duty bound, Mr. Ziegler exhibits all the intellectual prejudices of the sentimental-romantic school to which he belongs. He is, of course, anti-semitic, and is quite sure that "we Germans" are the metaphysical salt of a degenerate world. Also he prefers Richard Wagner to Shakespeare as an exponent of the tragic idea. From his somewhat sentimental point of view he has some interesting criticisms of ancient and modern tragedy. This is not the place to discuss his theory in detail, but one question may perhaps be put to him. On his view, so long as the tragic hero wills something passionately, it must be a matter of indifference what he wills. Richard III. or, for the matter of that, Bluebeard is as good a hero as Antigone or Othello. Now does not this position, to say the least of it, require some substantiation? With more reverent study of the great masters of tragedy and less rhetoric about the defects of the Jews and the superhuman excellences of the German genius, he may in future make a more valuable contribution to æsthetic theory.

A. E. T.

Hygiene for Students. By Edward F. Willoughby, M.D.Lond. Pp. xx + 563. (London: Macmillan and Co., 1901.) Price 4*s*. 6*d*.

THIS book, which is a fourth edition of the "Principles of Hygiene," although designed for the examinations of the Board of Education, covers a wide field, and should be of considerable value to medical practitioners and others who wish to gain a general knowledge of, without going deeply into, the subject. An excellent account is given of various dietetic substances, wines, tea, coffee, bread, meat, butter, &c., their actions, uses and adulterations. Some good advice is given respecting sleep and its attainment, but the suggestion that 5–10 grains of chloral may be taken in extreme cases of insomnia is decidedly one that should have been omitted. Ventilation and heating are dealt with more fully than is usual in books of the size; and there is a good account of drainage and sanitary appliances. Chemical methods for the disposal of sewage are condemned, while a concise account of the various bacterial systems is given. The author adopts a classification of his own of the specific infective diseases, which has many points to recommend it; and the information given seems to be well up to date, *e.g.* the transmission of malaria and of yellow fever by the mosquito. Altogether, the book is one which may be recommended, not only to the beginner, but also to the advanced student, for much information is introduced which is usually only met with in the larger text-books.

R. T. H.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Simple Telephonic Receiver for Wireless Telegraphy.

WHILST engaged in some testing experiments with an installation for wireless telegraphy (Popoff system) between the Hook of Holland and the Government lightship, lying at a distance of 16 km. from shore, it occurred to me to try telephonic communication. As the necessary apparatus, now constructed by different companies, could not be procured without much delay, I made myself a most simple arrangement, yet yielding excellent results, an account of which may interest those occupied in similar experiments.

I fixed two parallel pieces of carbon (as used in an ordinary arc lamp) having a length of 5 cm. on a square piece of wood, and made with it a circuit including a couple of dry elements (small size) and an Ader telephone; the circuit was completed by placing three or four common sewing needles loosely in transversal direction on the carbon rods. The apparatus is ready for use when the insulated wire of the signal mast (antenna) is joined to one carbon and the other is connected to the earth conductor. The letters from the Morse alphabet are very distinctly heard by this most simple device as shorter and longer taps in the telephone, and at the given distance the telegrams were easily read by sound, by a trained operator, as they were sent from the ship, and more quickly, of course, than they could be delivered by the usual coherer arrangement combined to the Morse writer; besides, it does not require special care to keep it in working condition. Yet it is sensitive enough to make audible the peculiar noise which accompanies the motion of the interrupter combined with the induction coil when it is operated by hand to produce the spark.

I believe that such a receiver may prove very useful for temporary installations of wireless telegraphy, as any one may carry it, along with all its accessories, in his pocket and put it at once in action when an insulated wire can be fixed to some elevated post, earth connections being always at hand.

I also investigated this arrangement in my laboratory with the view to ascertain whether it is really auto-decohering, as has been claimed recently for circuits where a telephone is used and carbon as coherer substance. Indeed, it seems that no tapping or any other arrangement is required to keep the telephone in good receiving condition. But when I substituted a sensible aperiodic galvanometer (Weston's construction) for the telephone, and operated with a small induction coil and Leyden jar (spark 3 mm.) in an adjacent room, every discharge produced a deflection of the needle, which did not return to its former position, unless a slight tapping was applied near the carbons, otherwise each new spark increased the deflection obtained by the former. It may be that the self-induction of the coil of the telephone is sufficient for decohering, which factor is not so active when a galvanometer is substituted.

I examined other substances than the steel needles, namely, copper, nickel, platinum, carbon, this also in powder (as used in the Mix and Genest telephone), and they all gave the same result, and this was obtained in the best way when, before the sparking of the coil, the transverse wire, by slightly tapping, had obtained a contact sufficient to transmit a small portion of the circuit current. But I observed that sometimes with platinum, and also with carbon, the deflection was reduced to zero, when the sparks set in, indicating that the resistance was increased by the electric waves, instead of diminishing, as was usually the case.

I found that a certain pressure exerted on the transverse wire, lying on the carbons, did not prevent the influence of the electric waves on the contact surfaces. When a load of 1·5 kg. and even of 5 kg. was placed on the needles (protected from immediately touching them by a glass plate), the deflection of the galvanometer set as well in and the telephone answered as distinctly to the sparks, produced in another room, as before.

It is obvious that the described arrangement proves also to be a very delicate microphone, but a slight pressure applied in the same way on the transverse wires makes it directly insensible to sound impulses, as was to be expected.

The Hague, July. L. BLEEKRODE.

The Future of the Victoria University.

PROF. SCHUSTER (p. 319) does not challenge the accuracy of my statements and I have nothing to alter in them. I have enjoyed reading his playful comments, but I have no desire to enter upon a mere dialectic contest with him, especially if it is to be fought with dynamical metaphors. I only wish now to disavow the predilection for federal universities, which Prof. Schuster artfully attributes to me. I have certainly acquired belief in one existing federal university which includes Lancashire and Yorkshire, but if that "experiment" is to fail, I do not see that I should necessarily favour another of the same kind. I must therefore decline with thanks the consolation that is offered me in the contingent possibility of my being able to take part in a federal university for Yorkshire. The immediate need of those who are or may be charged with university organisation seems to me to be an authoritative and impartial pronouncement on the causes which are alleged to warrant the disruption of the Victoria University. This is what I await before agreeing to any fresh experiment. ARTHUR SMITHELLS.

August 1.

M. Faye and the Paris Observatory.

I THINK the addition of the following to the excellent article on Hervé Faye in NATURE of July 17 (p. 277) is of interest. I had the facts from Le Verrier and Faye; they have not been reported in the speeches delivered, and should not be lost to history.

It is known that one of the great things done by Le Verrier was the creation of the Central Bureau of Meteorology, as part of the Paris Observatory. When the celebrated astronomer was dismissed, in 1870, by the Emperor, no change took place in the organisation of this establishment. When Le Verrier was recalled, in 1872, after Delaunay's accidental death, he filled, as in former times, the double position of head of French astronomy and of meteorology. But he was told that steps were being taken by the Administration to form a Central Bureau, independent of the Observatory, when he should have breathed his last. This idea grieved Le Verrier; he complained bitterly of it to his friends and to the Academy.

When Le Verrier died, M. Yvon Villarceau was appointed intermediate director, and filled this office for some months. M. Bardoux, a member of the Senate, sent a message to the Academy of Sciences asking its opinion on the idea of creating an independent "Météorologie." The question was warmly discussed in secret session, and M. Faye, like many others, raised objections. The Academy accepted their opinion, and answered in the negative to the official proposition. As the advice of the Academy was not binding, M. Bardoux had a right to disregard it, which he did. The reputation of M. Faye was such that he was generally considered as being the only possible successor of Le Verrier. M. Bardoux advised M. Faye to accept the directorship of French astronomy, as meteorology would henceforth form a separate department. M. Faye thanked M. Bardoux, but declined under such conditions.

WILFRED DE FONVIELLE.

Electrical Resistance of Iron at very Low Temperatures.

OWING to the kindness of Dr. M. W. Travers in providing me with some liquid hydrogen, I have recently been able to observe the resistance of a specimen of iron wire at a temperature of about 20° absolute. The specimen was the same that had been used in previous experiments on resistance between 1100° and −200°, and the result of continuing the resistance-temperature curve is of considerable interest. In two papers on this subject Profs. Fleming and Dewar reach the conclusion that the resistance of pure metals tends to vanish at the absolute zero, but that the presence of impurity in the specimen reduces the rate of decrease of resistance with temperature, and that this behaviour may even afford a test of the purity of a conductor. This bears out a remark made by M. Edmund Van Aubel (*Annales de Chimie et de Physique*, 1899) that the purity of bismuth can be gauged by the variation of its electrical resistance between 0° and 30°.

The temperature coefficient of bismuth is abnormal when the element is in certain physical conditions, its resistance increasing with fall of temperature in more than one position over the range indicated, a behaviour which is less surprising if bismuth really contains a small percentage of polonium. An observation

of resistance at the temperature of liquid hydrogen was made by Dewar on platinum, and he found that the resistance decreased to a certain value and then became constant. Thus from this result and from the behaviour of bismuth it is not altogether unexpected that a rather impure specimen of iron should show a definite turning power.

The present experiments, so far as they go, show that the resistance of iron at the temperature of -253° is actually greater than that at -191° (liquid air), a turning point on the curve occurring just below -200°. Several readings were taken of the resistance of the iron spiral when immersed in liquid hydrogen, and the readings in liquid air were consistent with my previous results. But the observations lack confirmation, and I am induced to publish them owing to the small chance of getting any more liquid hydrogen until next year. E. PHILIP HARRISON.

University College, London, July 31.

Retention of Leaves by Deciduous Trees.

I HAVE read with much interest the various communications in NATURE on this subject, as the phenomenon was the subject of much conjecture to me last winter in Northumberland. In one particular instance which I had constant opportunity of observing, the cause of the retention of the leaves could hardly have been "protection," as the beech hedge in question was in a very exposed, though by no means an elevated, situation. The hedge was a high one, probably 12 or 15 feet high, and formed a protection to the garden to the south or south-east of it, and in spite of the severe winds to which it was exposed it retained its leaves long after those of the beech trees of the neighbourhood had fallen.

I am inclined to think that it is much more probable that the frost theory brought forward by "P. T." in NATURE of May 15 is the true solution of the phenomenon than that the retention is a "protective device."

It would be interesting to know whether "P. T." or any other readers of NATURE can produce any further proof of early frosts causing the premature drying up of the leaves in the case of beech hedges and young small trees. If, as "P. T." suggests, the early freezing prevents the formation of the abscission layer of cork at the base of the petiole, it should also cause the leaves of hedges and small trees to display their autumn tints, or at least to show signs of drying up earlier than the leaves of the larger trees.

If this can be shown to be generally the case where the leaves are retained, I think "P. T.'s" theory would be considerably strengthened. A. F. G.

Henzada, July 1.

Campanulate Foxgloves.

IN the issue of NATURE for July 24 (p. 306) is a paragraph which is somewhat misleading. It is distinctly stated therein that "the terminal flower of each inflorescence was not a foxglove blossom, but a Canterbury bell (Campanula)," and again, "the combination of two flowers other than the foxglove and Campanula, if it occurs, would, however, be worth recording." There is no telling what hybridisers may do in the future, but it is quite certain they have not yet succeeded in crossing the foxglove with a Campanula, nor does it seem likely they will ever accomplish such a feat. Bigeneric hybrids (if they are really bigeneric) are not uncommon nowadays, but the union is always between nearly allied genera, not between groups so widely different one from the other as the foxglove and the Canterbury bell. The confluence of several of the uppermost flowers of the foxglove into a large cup-shaped blossom is not uncommon. Indeed, the peculiarity is so far "fixed" that a large percentage of the seeds from this form may now be relied on to "come true." Is this a case of the inheritance of an acquired character?

The synanthic condition of the foxglove flowers is mentioned in my "Vegetable Teratology," p. 40, or p. 59 of the German editions, and has repeatedly been recorded, but I am not aware that the cause of the deviation has been ascertained.

MAXWELL T. MASTERS.

Forestry.

IN my paper on forestry which appeared in NATURE of July 17 (p. 283) I was wrong in stating that *cueillettes* means "production of all kinds from baskets and fishing rods to sponges and caviare." The term means articles of forest produce, collected and utilised, though not specially made the object of the working of the forest.

Fruits and seeds, grasses, flowers, bark, medicinal products, and so on, all belong to *cueillettes*.

This correction is due to Mr. J. S. Gamble, F.R.S., who wrote the article in the Royal Scottish Arboricultural Society *Proceedings*, which I noticed in the paper referred to.

Coopers Hill, Englefield Green, Surrey. W. R. FISHER.

THE FORTHCOMING MEETING OF THE BRITISH ASSOCIATION AT BELFAST.

SECTIONAL ARRANGEMENTS.

THOUGH several of the sections of the British Association have not completed their programmes, it is possible to make a preliminary statement of some of the subjects to be brought before the Belfast meeting. Up to the time of going to press, the following particulars of sectional arrangements have reached us.

In Section A (Physics) there is to be a department in astronomy and cosmical physics, to be presided over by Prof. Schuster. To this department papers on the work on Eros, on the Moon and on Nova Persei will be presented, and some discussion on points connected with the nebular theory will, it is hoped, take place. Photographs from Yerkes Observatory will probably be shown, and several seismological communications will be made. In the section itself, Lord Rayleigh will probably raise the question of the conservation of weight in chemical reactions; Prof. Trouton will describe his experiments to detect the rotation of the ether with the earth, and Dr. Larmor will have something to say on the temperature of radiant energy. Belfast will be represented in the programme, Profs. Everett, Morton and Dixon having several communications to make.

The presidential address in Section C (Geology), by General C. A. McMahon, F.R.S., will deal with the general principles of rock metamorphism. Among the papers received or promised for the section are the following:—(1) "The Geology of the District around Belfast, including the Mourne Mountains"; (2) lecture on "The Structure of Ireland," by Prof. Grenville A. J. Cole; on "The Viscous Fusion of Rock-forming Minerals," by Prof. J. Joly, F.R.S.; "List of Minerals known to occur in Ireland," by Mr. H. J. Seymour; note on "The Scenery of Ceylon," by Mr. A. K. Coomaraswamy; on "A Lower Carboniferous Fish-fauna from Victoria, Australia," by Dr. A. Smith Woodward, F.R.S.; on "The Graptolites of the Belfast District," by Mr. R. Clark; on "The Valleys at the Head of the Hardanger Fjord, Norway," by Mr. H. W. Monckton; on "The Marine Fauna of the Boulder Clay," by Mr. Joseph Wright; on "The Original Form of Sedimentary Deposits," by Rev. J. F. Blake; on "A Stage in the Evolution of the Brittle Stars," by Prof. W. J. Sollas, F.R.S.; on "The Fishes of the Lower Devonian 'Roofing Slate' of Gemünden, Germany," by Dr. R. H. Traquair, F.R.S.

Prof. Howes is president of Section D (Zoology) this year, and it is believed that he will devote his address to a general consideration of the importance of the morphological method in zoology. As regards the subsequent work of the section, several papers of a morphological and more or less technical character have already been promised. The president will show, on behalf of Dr. Hill, an interesting series of photographs of segmenting eggs and other early stages in the development of Dasyurus. Prof. Johnson Symington will read a paper on the "Cetacean Larynx." Prof. MacBride will describe the development of Echinus, and Mr. Bles, whose exhibit of living larvæ of Xenopus (Dactylethra) excited so much interest at the Royal Society's soirée

recently, will give a general account of the development of this interesting frog. Mr. Graham Kerr will describe the result of his investigations on the early development of nerve and muscle in Lepidosiren.

It is hoped that Prof. Herdman will be able to contribute accounts illustrated by lantern of his recent experiences of "Dredging in the Indian Ocean" and "Life and Work on the Pearl-oyster Banks of the Gulf of Manaar." Several other papers from the Liverpool School are expected—by Mr. A. T. Watson, on a very interesting defensive mechanism which he has discovered in certain Onuphid worms; by Mr. I. C. Thompson, on Indian Ocean Copepods collected by Prof. Herdman; and by Mr. H. C. Robinson, on his recent journeys in the East. Mr. J. Stanley Gardiner will read a paper on the "Bionomics of a Coral Reef."

The International Fisheries Investigation scheme, the inauguration of which is exciting so much interest at present, will form the subject of papers by Prof. McIntosh and Mr. Garstang. Of similarly economic interest will be Dr. J. L. Jameson's account of his reinvestigation of the problem of pearl formation. Mr. J. Stuart Thomson will give an account of his recent researches on the scales of marine fishes as an index of age.

Prof. Cossar Ewart will communicate the results of his recent experiments upon intercrossing of dogs. Prof. Weldon, in one of the evening lectures, will deal with heredity. This subject is so much "in the air" at present that it is to be hoped that some further communications dealing with it may be presented to the section. In regard to faunological matters, Dr. Scharff will read a paper on the "Atlantis Problem," Mr. Carpenter on the "Insect Fauna of Irish Caves," and Mr. Steel will make an interesting exhibit of Australian specimens.

Among the papers which, it has been arranged, will be read in Section E (Geography) are the following:—Dr. H. R. Mill, on "Antarctic Expeditions"; Dr. J. Milne, F.R.S., on "World-shaking Earthquakes in relation to Volcanic Eruptions in the West Indies"; on "The Jordan Valley" and on "Petra," by Prof. Libbey, of Princeton University, N.J.; Prof. Johnson, Dublin, on "Peat"; Mr. C. R. Beazley, on "Mythical Islands to the West of Ireland"; Mr. R. L. Praeger, of the National Library of Ireland, on "Geographical Plant Groups in the Irish Flora"; the Rev. W. S. Green, on "Rockall and Porcupine Bank off the West of Ireland"; Mr. J. Porter, on "The Cork Valleys"; Mr. R. B. Buckley, C.S.I., on "Colonisation and Irrigation in Uganda and the British East Africa Protectorate"; Captain Ryder, R.E., on "Surveys in Yünnan"; and Mr. C. H. Hawes, on "The Island of Sakhalin and its Inhabitants." The general subject of the presidential address by Sir Thomas H. Holdich will be "The Necessity for the Application of more Scientific Methods to Geographical Exploration."

The president of the Engineering Section is Prof. John Perry, F.R.S., whose presidential address is looked forward to with interest. In this section it is expected that an important report will be presented by the Committee on Road Traction. The committee, the secretary of which is Prof. H. S. Hele Shaw, was appointed two years ago to investigate certain questions connected with the propulsion of vehicles on roads. The introduction of motor cars has made these problems of great importance, and one easily realises that much has to be done, remembering that scientific engineering was born long after the railways had absorbed all important traffic from the roads. The Screw Gauge Committee reported last year that it was transferring its work to the National Physical Laboratory, and the progress of this will probably be reported this year. Among the papers to be read are several on Irish water questions, on problems connected with steam raising, on electrical and surveying apparatus and on some subjects of mechanical detail.

The president of Section K (Botany), Prof. J. R. Green, F.R.S., will deal in his address with the present position of research in vegetable physiology and its importance in connection with agriculture. He will give a general account of some of the more important problems in this department of botany, and will endeavour to indicate certain lines of research which may be expected to have important developments in the future. The work of the section will include papers on "The Morphology and Past History of the Araucarieæ," by Mr. A. C. Seward, F.R.S., and Miss Sybille Ford; on "Internodes and their relation to Morphological Problems," by Prof. Percy Groom; on "The Dorsiventrality of the Podostomaceæ," by Mr. J. C. Willis; on "The Function of the Nucleolus" and on "The Nucleus of the Cyanophyceæ," by Mr. Harold Wager; on "Sex in the Genus Diospyros" and on "Foliar Periodicity in Ceylon Trees," by Mr. H. Wright; and on "Fossil Nipa Seeds from Belgium," by Mr. Seward and Mr. Arber. Papers will also be read by Prof. Oliver and Miss Chick, Dr. Dixon, Miss Matthaei, Miss Bateson, Mr. Worsdell, Prof. Bottomley and others, and Mr. Thomas Steel will exhibit some characteristic Australian plants.

The president of Section L (Educational Science), Prof. Henry E. Armstrong, F.R.S., will deliver an address on the morning of Thursday, September 11. The subjects to be brought forward in papers, addresses or reports with a view to discussion are:—"Recent Reforms in Irish Education, Primary and Secondary, with a view to their Coordination," by Dr. W. J. M. Starkie; "Report on the Teaching of Mathematics"; Irish Educational Work: (1) "Intermediate Education in Ireland," by Mr. R. M. Jones; (2) "The Introduction of Practical Instruction into Irish National Schools," by Mr. W. Mayhowe Heller; "Technical Instruction in Relation to Industrial Development in Ireland," by the Right Hon. Horace Plunket; "Report on Teaching of Science in Elementary Schools"; "The Training of Teachers," by Prof. Withers, Miss Walter and others; "Report on the Conditions of Health essential to the carrying on of the Work of Instruction in Schools"; "The Subjects to be Taught as 'Science' in Schools and the Order in which they should be Taken," by Dr. C. W. Kimmins; papers on "Educational Experiments"; "The Teaching of English," by Mr. P. J. Hartog, Canon Lyttelton and others; joint discussion with Section G on "The Training of Engineers"; and "Interim Report on Examinations."

The Belfast Harbour Commissioners have offered to lend their steamer *Musgrave* to the local committee for the use of members of the Association for Harbour and Lough trips on three days during the meeting, and it was suggested that on one of these days a special visit of the Engineering Section might be made to the Harbour Works. Supplementary excursions are being arranged by the Belfast Naturalists' Field Club, consisting of short trips in the neighbourhood in the afternoons during the meeting, and also longer excursions for the Thursday after the meeting. Ample information respecting all these will be obtainable in the reception room. On Thursday, September 11, the Lord Mayor of Belfast, Sir Daniel Dixon, D.L., will invite members, associates and holders of ladies' tickets to a reception in the exhibition hall near Queen's College. On Friday, September 12, the Earl of Shaftesbury invites members, associates and holders of ladies' tickets to a garden party in the grounds of Belfast Castle at the foot of Cave Hill at three p.m. (limited to 600). On Saturday evening, September 13, Major Ritchie and Miss Ritchie will invite 150 members to a reception at the Grove, at nine p.m. A list of lodgings and hotel accommodation has been prepared and may be obtained on application.

THE FIRST MEETING OF THE INTERNATIONAL COUNCIL FOR THE EXPLORATION OF THE SEA.

AT the conference which was held at Stockholm in June, 1899, having for its object the promotion of international cooperation in studying the physical and biological conditions of the seas bordering Europe, programmes were discussed and formulated, which were revised at the second conference, held in Christiania, in May, 1901, when a scheme for the coordination of the proposed work was provisionally agreed to. This scheme contemplated the creation of an International Council nominated by the Governments of the countries interested, which should meet periodically and organise and direct the proposed work, utilising for this purpose funds to be placed at its disposal by the Governments in question.

The question having been considered by all the maritime countries of northern Europe, all except France decided to participate, in most cases, however, for a few years only, and with conditions limiting the application of the funds which were voted to researches likely to produce practical results beneficial to fisheries at an early date.

The first meeting of the International Council took place in Copenhagen on July 22, when the following delegates and experts took part:—Great Britain, Sir Colin Scott Moncrieff and Prof. D'Arcy Thompson, with Dr. H. R. Mill and Mr. W. Garstang as experts; Denmark, Captain Drechsel and Dr. M. Knudsen, with Dr. C. G. J. Petersen and Dr. Ostenfeld as experts; Holland, Dr. P. P. C. Hoek; Finland, Prof Homén and Dr. Nordqvist; Germany, Dr. Herwig and Prof. Krümmel; Norway, Prof. F. Nansen and Dr. J. Hjort, with Mr. Schweigaard as secretary; Russia, Dr. Knipovich; Sweden, Prof. O. Pettersson and Dr. Trybom, with Prof. P. T. Cleve as expert. The Council was received at the opening meeting by the Prime Minister, M. Deuntzer, who welcomed the delegates to Copenhagen and explained that the Belgian Government, while not sending a delegate on this occasion, had not dissociated itself from the work. The King of Denmark received the delegates on a later occasion, and the Prime Minister and the Minister of Agriculture gave dinners in their honour. The meetings took place in the Foreign Office, and every possible facility was afforded for carrying out the work for which the Council had assembled.

At the first sitting the Council was constituted. Dr. Herwig, of Hanover, the head of the German Sea-Fisheries Association, was elected president; Dr. Otto Pettersson, of Stockholm, vice-president; and Dr. P. P. C. Hoek, of The Helder, in Holland, was appointed general secretary, in accordance with the suggestions of the Christiania conference.

The second sitting was occupied in discussions as to the management of the business of the Council, and two committees, each consisting of one delegate from each country represented, were appointed to draw up definite proposals as to the oceanographical and biological work of the Council. The third sitting received the reports of these committees and adopted them after discussion.

The scheme of biological work has been considerably modified on account of the conditions imposed by most of the Governments in giving funds for the international cooperation. Practical results of direct value to the fisheries are sought for, and the money has been given definitely for that purpose, thus preventing the institution of researches of a purely scientific aim the results from which might not directly and rapidly lead to the benefit of fisheries.

It was decided to undertake at once the systematic study of two problems of immediate practical importance—the migrations of the most important food-fishes of the North Sea, especially the cod and herring; and the question of over-fishing in those parts of the North Sea, Skagerrak and Kattegat most frequented by trawlers, with special reference to the plaice, the sole and other flatfish, and to the haddock. Each problem is to be studied by international observations directed by an international committee under a chairman or convener nominated by the Council. The committee on fish migration consists of one representative each of Germany, Denmark, Norway, Sweden, Finland and Russia, and two of Great Britain (for England and Scotland); the convener of this committee is Dr. Johan Hjort, of the Norwegian Fisheries Department. The committee on over-fishing consists of one representative each of Germany, Denmark, Sweden and the Netherlands, and two of Great Britain (for England and Scotland), to whom will be added eventually one of Belgium. The convener of this committee is Mr. W. Garstang, of the Marine Biological Association.

A third committee for the investigation of the Baltic was also appointed, consisting of one representative each of Germany, Denmark, Sweden and Finland, with Dr. Nordqvist as convener.

The "hydrographical," or, as we would rather term it, the purely oceanographical work of the international cooperation is to be carried out by means of the steamers provided by the participating States in accordance with the provisions of the Christiania programme. The representatives of the various countries handed in provisional schemes authorised by their Governments, the British scheme including two areas for research—the English Channel west of the Isle of Wight and the Færoe-Shetland Channel. The Dutch area includes the southern and the German area the northern half of the North Sea; the Danes undertake observations between Færoe and Iceland, the Norwegians observations in the western North Atlantic off the coast of Norway, and the Russians in the Arctic Sea. It is hoped that Belgium may undertake the eastern part of the English Channel. The countries possessing a coast-line on the Baltic divide that sea between them. The essential feature of the physical work consists of a simultaneous quarterly cruise by all the ships, employing instruments and methods of higher precision than have hitherto been thought necessary, and determining the horizontal and vertical distribution of temperature, salinity, dissolved gases and also of plankton. This does not, however, exhaust the programme, which provides for securing an extensive series of surface observations, and samples from regular liners crossing the North Sea and the Atlantic, and also aims at utilising lightships and coast-stations for regular observations at frequent intervals, in order to connect the various periodical cruises and so enable a continuous record of the march of seasonal change to be kept.

The International Council will conduct its work through the Central Bureau, which has now been established in Copenhagen, and the International Laboratory, to be opened in Christiania. The Bureau consists of the president, vice-president and general secretary of the Council, with the addition of Captain Drechsel, one of the Danish delegates, as an honorary member. It will exercise the executive authority of the Council, calling the annual or extraordinary meetings when required and keeping up communication with the various national organisations through the secretary, Dr. Hoek. The chief assistant in the Bureau is Dr. Martin Knudsen, lecturer on physics in the Polytechnic Institute of Copenhagen.

The International Laboratory at Christiania will be opened under Dr. Nansen, as honorary director, in the month of October, and Dr. Walfrid Ekman, of Stockholm, has been appointed first assistant, specially charged with the purely physical work; a second assistant for chemical work will be selected by Dr. Nansen at an early date. The work of the Laboratory, as defined in the Chris-

tiania programme, includes the instruction of observers, the verification of instruments, the preparation and distribution of standard sea-water for controlling analyses, and experiments with new apparatus.

As in all international undertakings, concessions have had to be made on all sides; but the proceedings at the Council were always harmonious, and there is good reason to expect that the various national organisations will cooperate heartily to obtain results which at the end of a few years may justify the experiment to the practical man engaged in fisheries as well as to the man of science.

H. R. M.

POLYNESIAN POLITICS AND ANTHROPOLOGY.[1]

IN the course of a long residence in the South Pacific as a British official, Mr. Basil Thomson has from time to time published several amusing and instructive works, illustrative of native life and thought and the book, however, and, to those who are interested in the well-being of the Pacific Islanders, the more pleasant part, is that which concerns the visit to Savage Island. The sovereignty of that island had been offered to Queen Victoria in 1887, and a protectorate so long ago as 1859. The island had been Christianised by the London Missionary Society, of whose missionaries, and particularly of Mr. Lawes, the resident missionary at the time of the proclamation, Mr. Thomson speaks in the highest terms. The natives were accordingly well-disposed towards the object of the visit; and the ceremony of proclamation of British supremacy was performed, and the protectorate flag hoisted, after the signature of a formal treaty, in the presence of a general assembly of the people, with their full assent.

Mr. Thomson took the opportunity of his visit to make inquiries into the history, customs and racial affinities of the natives. This was partly a business inquiry, for on coming under British rule certain changes in the law, particularly in the penal code, were requisite. It is only

FIG. 1.—A grave in Tonga.

problems with which a civilised Government has to deal. Not the least instructive, or the least amusing, of these was "The Diversions of a Prime Minister," issued in 1894. There the author recounted the difficulties which beset him in repairing the evils of the misgovernment of the Tonga Islands by Mr. Baker, formerly a Wesleyan missionary, and afterwards, as prime minister of the king, practically despot of the islands. The present volume narrates his experiences as commissioner for the purpose of taking over the suzerainty of Savage Island and Tonga consequent on the Samoa Convention with Germany, whereby these islands were assigned to Great Britain. So far as regards Tonga, therefore, it is a sort of sequel to the former work. The more important part of the one example of the intimate connection between anthropological study and the practical politics of the widely extended British Empire. Fortunate it was for the Savage Islanders that an official so experienced in the ways of the Polynesian and Melanesian races, and so sympathetic, was found to undertake these delicate duties.

To enumerate the various subjects of scientific interest briefly discussed by Mr. Thomson would be to make a pretty long list. It must suffice to mention only three or four. The first is the physical and mental characteristics of the Niuéans. Polynesians they are, but Polynesians with a dash of alien blood which has rendered them less indolent, more alert and enterprising, than others of Polynesian race. Another subject is that of the historical value of tradition. The author cites a Niuéan tradition of a Tongan invasion, and sets beside it the Tongan account of apparently the same event, as well as an

[1] "Savage Island: an Account of a Sojourn in Niué and Tonga." By Basil Thomson. Pp. viii + 234. Illustrated. 7s. 6d. net. (London: John Murray.)

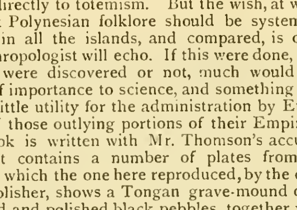
independent tradition of the Futuna islanders of an incident said by the Tongans to have occurred on that island during the same expedition. Whatever a critical examination of these traditions may yield, there is one caution to be observed. The Polynesians have an unusual facility for the preservation of quasi-historical memories. Their genealogies go back for many more generations than those of most other savages; and it is impossible to generalise from their example as to the historical value of the traditions of other races. Even their retention of the memory of events is capricious. The Niuéans have preserved a mimicry of the rite of circumcision, which renders it obvious that they once practised the rite in real earnest, like other South Sea islanders; but they have no tradition of how, or why, or when they abandoned it. The ceremony in question is curious, and, as Mr. Thomson says, probably unique. It is worth further inquiry. Lastly, the sacredness of animals, which is here noticed as a suggestion of totemism, is a clue to be followed up. There is nothing in the information given by Mr. Thomson pointing directly to totemism. But the wish, at which he hints, that Polynesian folklore should be systematically collected in all the islands, and compared, is one that every anthropologist will echo. If this were done, whether totemism were discovered or not, much would be discovered of importance to science, and something perhaps of not a little utility for the administration by European Powers of those outlying portions of their Empires.

The book is written with Mr. Thomson's accustomed gaiety. It contains a number of plates from photographs, of which the one here reproduced, by the courtesy of the publisher, shows a Tongan grave-mound of coral, white sand and polished black pebbles, together with the garlands worn by friends and suspended above it as a mark of their affection. Is the word "surplus" on p. 163 a misprint, or a joke?

E. SIDNEY HARTLAND.

KEW MICROMETER.

ALL botanists, entomologists and others who have to deal frequently with the minute measurements of parts of the object they examine must have felt the inconvenience of the double measurement involved in the use



of compasses and measuring rule. The instrument of which we give a figure has been named the Kew Micrometer, and has been devised by Sir Joseph Hooker to remove this inconvenience.

The construction will be evident on reference to the figure. By a simple adjustment of a scale to one arm of the micrometer, the length of an object is recorded up to a fraction and can be read off at leisure. One side of the scale is graduated to millimetres, the other to inches. For work under a microscope there is great advantage in the use of an instrument of this kind, for a measurement may be recorded and a dissection proceeded with without lifting the eye from the eyepiece of the instrument. Another useful feature of the micrometer is that the graduation to inches and millimetres on opposite sides of the scale furnishes a ready means of turning the one scale into the other without calculation, and this is a matter of some moment at the present time, when the two scales are in use in several countries. The length of the arm of the micrometer is exactly four inches, and this is graduated to tenths of inches and can therefore be used for larger measurements.

The instrument is a small and handy one, and can be easily carried in a sheath in the waistcoat pocket; it supplies a real want. Mr. Baird, scientific instrument maker in Edinburgh, is the maker of the instrument.

NOTES.

THE preliminary programme of the meeting of the German Association of Naturalists and Physicians to be held at Carlsbad in September has been prepared. On Sunday, September 21, the various committees will meet to transact the preliminary business in the forenoon, and the rest of the day will be devoted to social gatherings. Of the seventy-four meetings this will be the second visit paid to Carlsbad, the first occasion having been forty years ago. Prof. Dr. Heubner, of Berlin, is the president for this year, with Prof. Dr. van 't Hoff, of Charlottenburg, and Prof. Dr. Chiari, of Prague, as vice-presidents. On September 22 the work of the meeting will commence after an address of welcome to the general body, when Hoffmeister, of Strasburg, will deliver an address "On the Molecular Construction of White of Egg"; Weber, of Amsterdam, on "The Early History of the Malay Archipelago"; and Voller, of Hamburg, on "The Origin and System of Wireless Telegraphy." In connection with the last-mentioned, there will be during the week opportunities for the members to study the Slaby and Braun system, practical illustrations of which will be supplied by the General Electrical Co., of Berlin, and the Wireless Telegraphy Co. (Braun and Siemens-Halske system), of Berlin. On Wednesday morning the sections again unite to be addressed by Suess, of Vienna, "On the Nature of Hot Springs"; by Meyerhoffer, of Berlin, on "The Chemico-physical Constituents of Medical Springs"; and by Ruff, of Carlsbad, on "David Becher, the 'Carlsbad Hippocrates,' 1725-1792." At another general meeting on Friday morning lectures will be delivered by Baron von Eiselsberg on "The Importance of the Thyroid Gland in the Economy of Nature"; by von Wettstein on "Neo-Lamarckisms"; and by von Miller on "The Forces of Nature in the Service of Electricity." At the meetings of the 28 sections, the communications promised cover every field of investigation in natural science and medical and surgical practice, some hundreds of papers in all. On the scientific side they range up to 18 in the mathematical, astronomical and geodesy section, and 29 in the chemistry section, while on the medical side they range up to 60 in the surgical section. The closing meeting will be on Friday, September 25. Everything is being done by the ten local sub-committees to render the week a pleasant one for visitors, the Entertainments Committee having made a complete arrangement of concerts, theatricals, dinners and excursions to occupy the whole of the spare time.

PROF. D. J. CUNNINGHAM, F.R.S., has accepted the invitation of the Anthropological Institute of Great Britain and Ireland to deliver the third annual Huxley memorial lecture, the date fixed being October 21. He has chosen for his subject "Right-Handedness and Left-Brainedness."

THE San Francisco correspondent of the *Daily Mail* reports that the people of Santa Barbara, a county of southern California, are terror-stricken owing to the increasing frequency and severity of the earthquake shocks, of which there were seventy-

five from July 27–31. The most destructive was that at the town of Los Alamos, at 1.20 a.m. on July 31. All the brick buildings were thrown to the ground, but the frame buildings generally escaped serious injury except to their windows. Not a chimney has been left standing. The shock lasted thirty seconds, and seems to have had a spiral motion. Goods were hurled from the shelves of the stores and piled in the middle of the rooms; even heavy desks were tossed about. The inhabitants ran into the streets in a panic, for in the morning between 7.25 and 7.30 there were three additional shocks, and just before nine two more. It is also reported that there were four severe shocks of earthquake in Los Alamos Valley on August 1. Several buildings which had survived the earlier shocks were badly cracked, and an immense stiucture near Los Alamos was turned partly round on its foundations. The earth continues to tremble at intervals, and the countryside is said to be changing appearance. A Reuter telegram from Leiria, Portugal, states that a violent earthquake shock was felt there at midnight on August 3 and was renewed at 6.45 a.m. on August 4. One shock was felt throughout the centre of Portugal and on the seaboard. The Central Meteorological Bureau of Italy announces that a severe earthquake shock was felt at Carrara at 11.35 p.m. on Monday, August 4. It was followed by two more shocks. Another earthquake shock is reported from Massa. The seismographs at Siena, Florence, Padua, Rome and Rocca di Papa also registered disturbances.

In the House of Commons on Monday, the decision to close the observatories at Ben Nevis and Fort William was again brought forward, and the First Lord of the Treasury was asked whether he would order an inquiry to be made into the distribution by the Meteorological Council of the annual grant of 15,300*l*., so as to secure that an adequate allowance be made to these observatories. In his reply, Mr. Balfour referred to an inquiry held about twenty years ago, at the close of which the committee recommended that the inquiry should be repeated from time to time, a recommendation that has not been followed. In the circumstances he thought it would be right to have an investigation and to repeat it from time to time. This would involve no slur or slight on the scientific committee which allocates the funds.

A copy of the remarks made upon the subject of the Ben Nevis observatories by Sir Arthur Mitchell, honorary secretary of the Scottish Meteorological Society and of the directors of the Ben Nevis observatories, at the meeting of the Society on July 23, has been received. It is pointed out in this statement that the importance of observations at a high level is emphatically and increasingly recognised in the countries of Europe and in the United States of America. Both the high- and low-level observatories at Ben Nevis have been, all through their existence, under the sole management and control of the directors, by whom they were erected and to whom they belong. Having high-level observations to compare with suitably associated observations at sea level has a direct bearing on the study of meteorology broadly; but it is also and everywhere held that the possession of such observations may be reasonably expected to assist directly in weather forecasting. The directors started in 1883 with the intention of performing a big and costly experiment in atmospheric physics, which, in their opinion, ought to cover a sun-spot period, that is, from eleven to twelve years. This experiment they have been able to complete by the aid of public generosity. For the first seven years after 1883, when the observatory at the top of Ben Nevis was opened, there were no hourly observations at sea level for purposes of comparison, so that the experiment began in a complete form only twelve years ago, in 1890, when the low-level observatory at Fort-William was also opened.

The Museum of Practical Geology, Jermyn Street, will be closed as usual from to-morrow evening, August 8, until the morning of September 10.

The Reale Accademia dei Lincei has conferred on Mr. Marconi a special prize of ten thousand francs under the Santoro foundation in recognition of his work in connection with wireless telegraphy.

The Bisset Hawkins gold medal of the Royal College of Physicians of London has been awarded to Dr. W. H. Power, F.R.S., principal medical officer to the Local Government Board. The medal was instituted in 1896 with the object of perpetuating the memory of the late Dr. Francis Bisset Hawkins, and is bestowed triennially on some duly qualified medical practitioner who has, during the preceding ten years, done good work in advancing sanitary science or in promoting public health. Dr. David Ferrier, F.R.S., will deliver the Harveian oration of the College on St. Luke's day, October 18. The Bradshaw lecture will be delivered in November by Dr. C. J. Cullingworth. Dr. A. S. F. Grünbaum has been appointed Goulstonian Lecturer and Dr. T. R. Glynn Lumleian lecturer for 1903, and Dr. J. R. Bradford the Croonian lecturer for 1904.

On Friday last Sir Alfred Jones, chairman of the Liverpool School of Tropical Medicine, entertained at dinner the Duke of Northumberland and the Tropical Diseases Section of the British Medical Association, at the Adelphi Hotel, Liverpool. In proposing the health of the Duke of Northumberland, Sir Alfred Jones mentioned that a friend had given a donation of 25,000*l*. for the study of tropical medicine at the Liverpool School, and through the energy and perseverance of Prof. Boyce the School was being endowed with 10,000*l*. The Duke of Northumberland, in replying, said that he had been impressed with the importance of the efforts which were being made in the direction of ameliorating the conditions of tropical existence. In responding to the toast "Tropical Medicine," Sir W. Kynsey said it seemed extraordinary that in a wealthy country like England it was impossible to get a penny from Government for these schools, which had been entirely dependent upon private benevolence.

The steamer *America*, with the whole of the Baldwin-Ziegler Arctic expedition, arrived on August 1 at Honningsvaag, in Northern Norway, and then proceeded to Tromsoe. Mr. Evelyn B. Baldwin, the leader of the expedition, reports as follows to Reuter's Agency:—"This year's work has been successful. An enormous depot of condensed foods has been established by sledge on Rudolf Land within sight of the Italian expedition's headquarters. A second depot has been formed in lat. 81 33, and a third depot at Kane Lodge, Greely Island, which has been newly charted as near the 81st degree of latitude. These large depots, together with the houses and stores left at Camp Ziegler, as well as provisions for the five ponies and 150 good dogs now on board, besides the pack itself, will afford means for a large Polar dash party next year. The fact that all the channels through Franz Josef Land remained blocked by ice during the autumn of 1901 prevented the establishment of depots by steamer last year. The breaking up of the ice early in June compelled us to use our reserve supply of coal, and hence our departure from Camp Ziegler on July 1 in order not to imperil the expedition. We dispatched 15 balloons with 300 messages in June. We have obtained the first moving pictures of Arctic life. We discovered Nansen's hut, recovering the original document left there and securing paintings of the hut. We have also secured marine collections for the National Museum, new charts, &c. Thirty men, with 13 ponies, 170 dogs and 60 sledges, were employed in field work from January 21 to May 21, this severe work resulting in the destruction of the sledges; this and the depletion of the food for the ponies and the dogs rendered a return imperative."

IN a paper read at the International Navigation Congress recently held at Dusseldorf, Mr. Gordon C. Thomas, C.E., gives a description of a novel kind of canal lift which he has recently constructed at Foxton, on the Grand Junction Canal, one of the most important arterial waterways in this country. At Foxton there is a rise of 75 feet, which used to be overcome by a flight of 10 locks, which could only take barges carrying 33 tons. The time occupied in passing a boat through these locks was 75 minutes, and 30,000 gallons of water were used for the purpose at each lockage. The increasing traffic necessitated some better means of raising and lowering the barges and decreasing the quantity of water required. For this purpose Mr. Thomas has recently constructed for the Canal Company a new system of elevation at a cost of 40,000*l.*, by means of which the time occupied in raising and lowering the boats has been decreased to twelve minutes for one boat ascending and another descending as compared with an hour and a quarter for the passage of a single boat, the quantity of water used being only one-tenth of that required when the locks are used. The lift consists of an inclined plane connected with the higher and lower levels of the canal at an angle of 1 in 4. On this incline two docks, or iron troughs, 80 feet long, 15 feet wide and 5 feet deep are hauled up and down, the barges being first floated into or out of the docks from the canal, the ends of which are closed by gates made watertight. The troughs are hauled up sideways and the wheels on which they rest are so adjusted that the water in them always remains level. As one trough is drawn up, either loaded with a boat or empty, except as to the water, the other descends. This lift is capable of passing 200 canal boats in twelve hours, and can be managed by three men.

SIGNOR FILIPPO EREDIA has published in the *Atti* of the Royal Academy of Acireale some interesting statistics in regard to the rainfall of Sicily during the period 1880-1900. Considering the following ten stations, Palermo, Termini, Messina, Riposto, Catania, Syracuse, Mineo, Girgenti, Caltanisetta and Trapani, it is found that if the twelve months of the year be arranged in descending order of their average rainfalls, the five least rainy months at each station occur in the order September, May, August, June, July. The most rainy month is November for Messina, Riposto, Catania and Trapani, and December for the other stations. The next in order is December for Messina and Trapani, November for Syracuse, Termini and Girgenti, and January for the other stations. October occurs fourth on the list for Palermo, Termini, Girgenti and Syracuse; it is the third for Messina and Trapani, fifth for Riposto and Catania, and still lower down for Mineo and Caltanisetta. February is fifth on the list for Palermo, Termini, Messina, Trapani and Syracuse, fourth for Catania, Mineo and Caltanisetta and third for Riposto. Finally, March and April occupy the sixth and seventh places at all stations except Girgenti, Mineo and Caltanisetta.

THE director of the International Bureau of Weights and Measures, at Paris, has recently issued a further volume of he *Travaux et Mémoires* of the Bureau (vol. xii., 338 pp.; Paris: Gauthier-Villars.) This volume deals with (1) the determination in 1894-5 of the length of the yard in terms of the metre; (2) with the verification in 1890-7 of standard end-measures (mètres à bouts); and (3) with a comparison of platinum and gas thermometers. The volume also contains a reprint of the "Compte rendus des Séances" of the three general conferences on weights and measures which were held at Paris in 1889, 1895 and 1901, to the last of which reference has been recently made in our columns. The comparisons of the yard and metre, and the verification of the end-metres (1) (2), are now almost ancient history, and the important results obtained in 1895 and 1897 have been duly recognised in this country. A full and interesting report is made on the comparisons of platinum, gas and mercurial thermometers by Dr. J. A. Harker and Dr. P. Chappuis (3). The results of their researches have, however, been already published in London (*Phil. Trans.* Roy. Soc., vol. cxciv. pp. 37-134, 1900). Prof. Callendar's method of measuring temperatures based on the determination of the electrical resistance of a platinum wire, has been extended to a comparison at the Bureau of the platinum thermometer with the nitrogen thermometer (now adopted as the international standard thermometer) at temperatures varying from 80° to 460° C. A comparison was also made between the platinum and the mercurial thermometers at lower temperatures, all the comparisons having been made under the direction of Dr. Benoit. These comparisons were originally proposed by the Kew Observatory Committee, and the numerous formulæ as well as the results are clearly set out in appendices to the report.

THE explosion of a charge of about ten tons of gunpowder in connection with blasting operations in the granite quarries near Baveno (Lago Maggiore) has afforded Dr. Emilio Oddone an opportunity for making a series of observations of interest in connection with seismology, and the results are described in a paper communicated to the Istituto Lombardo in May last. The charge was fired on October 30, 1901, and Dr. Oddone made observations in a hut distant about 1¼ kilometres to the north of the mines, using a seismometer for horizontal motions, an apparatus for determining the relative motion in a radial direction of two points three metres distant, a variometer for the aerial disturbances, an aneroid and a chronometer. To calculate the velocity of propagation, observations were made at 7, 10 and 20 kilometres, and also with the instruments at Pavia, Milan, Turin and Padua. The indications of the seismograph showed initially a solitary wave of amplitude 0·1 millimetre, but in consequence of the rock subsequently breaking off in five pieces this was followed by subsidiary waves. The variometer indicated an instantaneous variation of atmospheric pressure of about 1/24 millimetre of mercury. The distant observations gave negative results; at Baveno, 7 kilometres distant, no earth tremors were noticed, and even the sound of the explosion hardly reached 15 kilometres. A calculation of the total energy dissipated by the waves across a hemispherical surface of radius 1500 metres about the hypocentre gives $1 \cdot 4 \times 10^7$ kilogrammetres, the total energy set free by the combustion of the powder being $2 \cdot 584 \times 10^9$ kilogrammetres. It appears, however, probable that about 92 per cent. of the elastic energy was absorbed at a distance of 1500 metres, and this absorption Dr. Oddone attributes to the viscosity of the granite. The same cause accounts for the absence of any observed earth tremors a t the distant stations, which made it impossible to calculate the velocity of wave propagation. At the same time, an explosion high up on a mountain at the side of a deep lake hardly appears to be favourably placed for sending earth-tremors to a long distance.

A BEAUTIFULLY illustrated pamphlet, by Mr. C. Dixon, issued by Ross, Ltd., of New Bond Street, describes the advantages of Ross's prism field-glasses to the out-of-doors naturalist.

NUMBER ix. of the L.M.B.C. *Memoirs*, by Mr. O. V. Darbishire, is devoted to a full account of the natural history of Chondrus, or "Irish moss." At the conclusion of his memoir the author deplores the want of a thoroughly trustworthy and up-to-date work on British sea-weeds.

THE August number of the *Contemporary Review* contains an interesting article on bird-life by Mr. Digby Pigott, in which the author draws special attention to the beautiful preparations in the Natural History Museum illustrative of the arrangement of the feathers in the wing.

THE *Journal* of the Straits Branch of the Royal Asiatic Society for January contains a long paper on Sarawak Hymenoptera, by Mr. P. Cameron, largely based on the collection made by Mr. R. Shelford. Since the report in 1857 on Dr. Wallace's collection very little work has been done on this subject, and the author is enabled to record a number of new generic and specific types.

THE contents of the July number of the *American Naturalist* include a paper on the gastrulation of the egg of the toad *Bufo lentiginosus*, by Miss H. D. King, and another, by Mr. W. A. Hilton, on the sense-hairs of caterpillars. In the latter the author states that the majority of the body-hairs of these larvæ are sensory, and that almost the only mode in which sensory nerves terminate on the bodies of insects is by means of hairs.

IN the July issue of the *Journal of Anatomy and Physiology*, Dr. H. W. M. Tims discusses the intricate question of the homology of certain deciduous and permanent cheek-teeth in mammals, in the course of which he disputes the view that the functional teeth of marsupials belong to the deciduous series. In the same number Mr. Elliot Smith describes the manner in which the desiccated brain is preserved in many Egyptian human skulls, other than those of mummies, and Prof. F. G. Parsons figures some of the leading modifications of the aortic arch in mammals.

THREE interesting instances of abnormality in mammals are recorded in journals received during the past week. In the *American Naturalist* for July Mr. F. Howe discusses the nature of the polydactylism in a breed of cats kept at Cambridge, Mass. It is concluded that the polydactylism lends no support to the theory of reversion to a six- or seven-toed ancestral type, the only definite statement possible being that three digits are developed where there are normally but two. In the *Journal of Anatomy and Physiology* for the same month Prof. O. C. Bradley records the occurrence of seven cheek-teeth, exclusive of the deciduous first premolar, in a horse, while Mr. Elliot Smith mentions an ancient Egyptian skull with an additional incisor. Mr. Smith, from his specimen, suggests that the missing incisor in man is *i.* 1, and not *i.* 2, as Tomes believes to be the case. It may be pointed out that Lydekker suggested the missing tooth to be *i.* 2 in 1884, or fourteen years earlier than the work of Tomes cited by the author.

AT the conclusion of some notes in the *Proceedings* of the Philadelphia Academy on the so-called flying-lemur (*Galeopithecus volans*), a creature usually regarded by naturalists as an aberrant member of the Insectivora, Dr. H. C. Chapman sums up as follows:—"It appears, at least in the judgment of the author, that Galeopithecus cannot be regarded as being either a lemur, or insectivore or bat, but that it stands alone, the sole representative of an ancient order, Galeopithecidæ, as Hyrax does of Hyracoidea. While Galeopithecus is but remotely related to the Lemuroidea and Insectivora, it is so closely related to Chiroptera, more particularly in regard to the structure of its patagium, brain, alimentary canal, genito-urinal apparatus, &c., that there can be but little doubt that the Chiroptera are the descendants of Galeopithecus, or more probable that both are the descendants of a Galeopithecus-like ancestor."

IN a valuable series of observations on living brachiopods contributed to the *Memoirs* of the Boston Natural History Society (vol. v. No. 8), Prof. E. S. Morse quotes with approbation a note from NATURE of July 13, 1899, based on Prof. J. A. Thomson's inaugural address at Aberdeen, on the importance of "nature-study," and he gives as one of the reasons for publishing his observations, which were made twenty years ago, our lack of knowledge of the habits of living brachiopods. It is not that these animals cannot be easily kept in confinement, as Prof. Morse states that in the middle of summer he transported a series of specimens a distance of 700 miles in a small bowl. In this connection it is interesting to note that from its vitality in such unfavourable circumstances Prof. Morse was led to suggest that the long persistence of Lingula might be accounted for. A few weeks ago we chronicled the very same suggestion made by Mr. N. Yatsu, of Tokio. The memoir is illustrated by twenty beautifully executed plates, of which the first is coloured.

WE have received the Report of the American Museum of Natural History for 1901, containing a full account of the rapid progress made by that institution and of the various expeditions which have been equipped by private persons for its enrichment. Among the latter is the Jesup expedition to the North Pacific, which has resulted in the acquisition of a mass of material illustrating the life of the Chukchi's of the extreme north-east of Siberia. The cost of publishing the results of this and other expeditions has become a somewhat serious difficulty. "It does not seem proper," says the Report, "to ask those who have generously placed parties in the field also to provide the funds for publishing the scientific results of their investigations; on the other hand, the general funds of the Museum are not sufficient to meet the obligation." As usual, the Report is well illustrated. A plate of the new "auditorium," with its benches crowded with attentive listeners, illustrates a phase of museum development unknown in our own metropolis. Among other illustrations is one of a group of guillemots and gulls mounted in the Museum in imitation of their natural surroundings. A second displays a remarkably fine skeleton of a fish-lizard (Ichthyosaurus) containing numerous young skeletons within the ribs, recently acquired by exchange with the Stuttgart Museum. Other plates are devoted to ethnographical specimens.

A FORTNIGHT'S cruise in the North Sea was made recently by the Norwegian Government's research steamer *Michael Sars*. The first week was spent in a series of studies on the distribution of animal life at various depths on "Storeggen" and "Shetlandseggen," which are great submarine ridges with sloping sides. With a 50-feet trawl dredgings were made down to a depth of 600 fathoms to ascertain the distribution at various depths of the fishes used for food. A sharply defined boundary manifested itself between the distribution of the food-fishes and the deep-sea forms of life, and this boundary coincides with a rapid transition from water of a higher temperature to water just above or at the freezing point. This boundary occurs on the slope of the Shetland ridge, at a depth of between 275 and 300 fathoms. A series of studies was next undertaken on the steep north-east slope of the Faero bank. Here, so far as is known, no accurate soundings had been previously taken and no fishing carried on either here or upon the great ridge or upon the Shetland ridge. A series of soundings was made, which do not correspond with those given on the British charts. Experimental fishings were carried on for three days with most satisfactory results; nine lines were cast, with a total of 5500 hooks attached to them, of which 660 were halibut hooks; and the catches consisted of 117 halibut weighing more than 5000 kilos., 300 large cod, 500 brosme, 10 common ling and 80 blue ling. This result is of interest, as it points to a new and important area for sea-fishery and to the existence of large quantities of halibut at a time of the year when it is not to be found on the great bank or ridge on the coast of Norway, and the same applies to the cod also. Both cod and halibut had herrings in their stomachs, although the catch was made at a depth of 200 fathoms. The work was carried out under the personal supervision of Dr. Johan Hjort.

ATTENTION was directed in NATURE for April 3 to a memoir by Prof. Yoshiwara on the geology of the Japanese islands which form the "Riukiu Curve." We have since received a report on the fossils of these islands and of Formosa, by Mr. R. B. Newton and Mr. R. Holland (*Journ.* Coll. Science, Tokyo, Japan, vol. xvii. 1902). The specimens comprise many examples of Orbitoides and other foraminifera, together with one or two species of Cellepora and one nullipore. They occur in the Orbitoidal limestone of Miocene age, and in the raised coral-reef formations which belong to some part of the post-Pliocene series.

A SECOND and enlarged edition of the "Hand-List of Herbaceous Plants" cultivated in the Royal Botanic Gardens at Kew has been issued. In the preface it is pointed out that no substitute for the "Students' Garden"—the site of which was required for the new wing of the herbarium—is contemplated, more especially since the Botanic Gardens at Chelsea have been reconstituted under the auspices of the Charity Commissioners to serve a similar purpose. A new feature in this edition is a reference to works in which figures of the species may be found.

OF the various subjects reviewed by Mr. J. H. Maiden in his presidential address to the Linnean Society of New South Wales, the forestry question and a botanical survey of the country are topics on which the opinion expressed is that of an indefatigable worker and a practical expert. In connection with the State management of forests, Mr. Maiden directs attention to the importance of conserving areas which are not suited to agriculture, and to the necessity for planting trees to check the sand-drifts and to provide shade on the arid western plains. The object of the botanical survey would be to summarise existing records and extend them. In order to institute a survey which shall be carried on by independent workers, the delimitation of the country into areas, whether known as *domaines* or *counties*, is essential; otherwise a definite basis for concerted action is wanting. A tentative scheme of botanical counties is outlined in a chart which accompanies the paper.

WE have received two papers dealing with insects harmful to agriculture, horticulture, &c., the one, by Mr. G. H. Carpenter, on injurious insects observed in Ireland in 1901 (*Economic Proceedings* of the Royal Dublin Society, vol. i. part 3, No. 5), the other by Signor A. Berlese, entitled "Importanza nella Economia Agraria degli Insetti Endofagi," published in *Bolletino* No. 4 of the Royal College of Agriculture of Portici, Sicily. In the former Mr. Carpenter states that entomologists appear to have paid scarcely any attention to the maggots of flies which infest the bodies of live sheep, and he has therefore considered it advisable to describe in some detail the life-history of the sheep-fly (*Lucilia sericata*). It is somewhat remarkable that this infestation seems to be mainly confined to Great Britain and Ireland, having been recognised on the continent only in France and Holland; in the latter case, at any rate, there is good reason to believe that it was introduced from England. The author also records the occurrence of a "plague" of black ants of the Tropical American species *Iridomyrmex humilis* near Belfast in 1900. In the second communication Signor Berlese describes, with figures, the life-history of a number of deleterious insects met with in Sicily.

THE Maidu stock of north-eastern California contains some very primitive tribes, who, in their lack of clan organisation or totemic grouping, practical absence of clothing and other negative characteristics, recall the Seri Indians of the Gulf of California as set forth in the elaborate study by Dr. W. J. McGee (Seventh Annual Report of the Bureau of American Ethnology). Mr. Rowland B. Dixon, when on the Huntingdon California Expedition, made a large collection of Maidu myths, which he has recently published in the *Bulletin* of the American Museum of Natural History (vol. xvii. 1902, p. 33). The time has not yet come when these myths can be made to yield general conclusions, more field-work being necessary in other districts. When such material is available it will probably enable us to trace more accurately the lines of migration and the mutual relationships of the great mass of stocks scattered along the Pacific coast from the Columbia River to Mexico. These myths are beast-tales with, or without, a human element. The coyote is very prominent; he seems to be generally inimical to mankind, and appears often as a buffoon and trickster, who comes out of his adventures in a sorry plight.

GERMAN translations of Faraday's papers on experimental investigations in electricity, from the *Philosophical Transactions* of 1835 and 1838, are given in Nos. 126 and 128 of Ostwald's admirable series of scientific classics published by Mr. W. Engelmann, Leipzig. Dr. A. J. v. Oettingen is the editor of the volumes, and contributes a few remarks upon them. No. 125 of the same series, edited by Dr. F. G. Donnan, contains translations of John Mayow's papers on nitre, combustion and respiration, and No. 124 papers on thermodynamics by von Helmholtz, edited by Prof. Max Planck.

THE additions to the Zoological Society's Gardens during the past week include two Green Monkeys (*Cercopithecus callitrichus*) from West Africa, presented by Captain Hugo B. Burnaby; a Common Otter (*Lutra vulgaris*) British, presented by Mr. W. Radcliffe Saunders; a Common Seal (*Phoca vitulina*) from British Seas, presented by Mr. H. C. Rouch; three Mauge's Dasyures (*Dasyurus viverrinus*) from Australia, presented by Mr. Paris K. S. Foot; eight Rufous Tinamous (*Rhynchotus rufescens*) from Brazil, presented by Colonel Sir Thomas Hungerford Holdich; a Common Mynah (*Acridotheres tristis*) from India, presented by Mrs. Hope Robinson; a Greater Black-backed Gull (*Larus marinus*) European, presented by Mrs. V. H. Veley; a Yellow-eyed Babbler (*Pyctorhis sinensis*), two Striated Babblers (*Argya earlii*), two Himalayan Black Bulbuls (*Hypsipetes psaroides*), three Rufous-bellied Bulbuls (*Hypsiptes maclellandi*), a Verditer Flycatcher (*Stoparola melanops*) from British India, presented by Mr. E. W. Harper; a Rough-scaled Lizard (*Zonurus cordylus*), a Spotted Gecko (*Pachydactylus maculatus*) from South Africa, presented by Mr. R. Broome; six Menopomas (*Crypotobranchus alleghaniensis*), four Menobranchs (*Necturus maculatus*), a Blue Lizard (*Gerrhonotus coeruleus*), a Spiny-tailed Mastigure (*Uromastix acanthinurus*), four Horned Lizards (*Phrynosoma cornutum*) from North America, deposited: a Bennett's Wallaby (*Macropus bennetti*), three Glossy Ibises (*Plegadis falcinellus*), three Jameson's Gulls (*Larus novae-hollandiae*), a Herring Gull (*Larus argentatus*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE SPECTROSCOPIC BINARY β CEPHEI.—In No. 5, vol. xv. of the *Astrophysical Journal*, Prof. Frost gives the results of his own and Mr. W. S. Adams's estimations of the radial velocity of β Cephei, reduced from ten spectrograms which these observers obtained between December 18, 1901, and May 24, 1902, with the Bruce spectrograph.

The results obtained by the two observers agree very well and indicate a radial velocity which varies from $-20\cdot3$ to $+11\cdot3$ km. It was expected that the period of variation would be found to be a long one, but two spectrograms obtained with an

interval of five and a half hours show a variation in velocity of about 14 km., or nearly half of the whole range yet observed.

Double Stars.—As an extract from the *Monthly Notices* R.A.S. for May, 1902, the Rev. T. E. Espin publishes his micrometrical measures of double stars made at the Wolsingham Observatory with a $17\frac{1}{4}$-inch reflector.

The catalogue contains several records of new components, such as in Σ 59, where two new components, C and D, have been observed, and Σ 3010, where a third component has been observed for the first time. There are also several variations of distance and position angle noted, and new values given to them, *e.g.* in Σ 2708 the measures made by Mr. Espin vary considerably from those made by the discoverer of this system, Prof. Hall, but this discrepancy is accounted for by a movement of 0″·26 towards 137°·7 which has been observed at Wolsingham. In regard to θ Persei (Σ 296) it is stated that the proper motion during the last 116 years has been perfectly rectilinear, all the observations being well represented by

$$\Delta = 16''\cdot363 + 0''\cdot029\,(t - 1866\cdot0).$$
$$T = 297^\circ\cdot162 + 0^\circ\cdot075\,(t - 1866\cdot0).$$

It has been observed that Σ 1321 is a similar system to 61 Cygni, P.M., the two components A and B both being of a reddish-yellow colour, whilst a third component, too faint to measure, was discovered on January 22, 1901.

Light of the Galaxy and Bright Stars.—In No. 3803 of the *Astronomische Nachrichten*, Mr. C. Easton gives the results of his researches in comparing the light of the Galaxy to that of the comparatively bright stars of the Milky Way of the Northern Hemisphere.

Mr. Easton divided the galactic zone between -18° galactic latitude and $+18^\circ$ galactic latitude into 108 rectangles, and then, by an ingenious method, compared the light emitted from the area of each rectangle with the light emitted by the stars of the Northern Milky Way. The results show that there is a correlation and parallelism between the distribution of the galactic light and the stars of Argelander. On this basis Mr. Easton deduces that the stars in general may not simply be isolated units, but they may all belong to such agglomerations as we believe make up the Milky Way, the only real difference being in their relative distances from us; he suggests that the apparently crowded parts of the heavens, such as occur in the region of Cygnus, are parts where we get two such agglomerations at different distances, overlapping at the edges, and supports this theory by noting the fact that in such regions, both the galactic light and the brighter stars increase in density together.

Periodicity of Volcanic Eruptions and Earthquakes.—*Circular* No. 49 of the Wolsingham Observations contains a summary, by the Rev. T. E. Espin, of the results obtained by arranging and charting the data which he has collected in regard to the times of volcanic eruptions and earthquakes.

These results point to a period of between eight and nine years in the phenomena of which Mr. Espin has received the records.

This period agrees with the period of revolution of the moon's perigee, and further investigation indicates that the greatest volcanic activity takes place when the perigee occurs at its maximum northerly declination.

Minor Planets.—Prof. Max Wolf records the observations, during July, of six minor planets, giving their R.A., declination and magnitude. Amongst them is a new minor planet 1902 JL, the position of which on July 9, 1902, at 12h. 13·7m. (Heidelberg mean time) was R.A. = 20h. 25·9m., Decl. = -19° 58′, and the daily movement of which is $-$ 0m.·8, $-6'$ (*Astronomische Nachrichten*, No. 3803).

PHARMACOLOGY AT THE BRITISH MEDICAL ASSOCIATION.

THE section of pharmacology at the British Medical Association at Manchester this year was distinctly active, and many interesting discussions were held and papers read. The first day's discussion was devoted to a subject of great practical value to physicians, viz. the unexpected and undesired effects of medicines. Sir Lauder Brunton introduced the discussion and his paper was full of interest. He treated at length the various factors which tend to render medicines either ineffective or productive of unusual effects. Speaking of tolerance, he instanced a case in which as much as 24 grains of morphine was used by a patient as a hypodermic injection, the ordinary dose being one-third of a grain. Taking arsenic as an example, he showed how the form in which this was given greatly influenced the results produced by it. The influence of certain remedies in producing skin rashes, especially those of the antipyrin series, was also referred to, and finally the occasionally extraordinary effects of some of the antitoxin sera; especially in this connection antistreptococcic serum was referred to as having in a few minutes produced in a patient an almost universal swelling of the subcutaneous tissues (general œdema). The varying effects of opium were, according to the lecturer, most probably to be explained by the inconstant chemical composition of this substance and its preparations.

Subsequently several papers were read. One which aroused great interest was communicated by Prof. Liebreich, of Berlin, upon the therapeutic value of alkaline waters of the Vichy type. The lecturer refused to believe that waters artificially made from the data of chemical analysis were of the same therapeutic value as the naturally occurring waters. Especially in this connection was the presence in natural waters of a substance of colloidal nature, known as glairin, of importance. In continuation, the lecturer indicated the special conditions for which Vichy waters were to be recommended. In the discussion which ensued, Prof. Tunnicliffe drew attention to the work of Nageli, Locke and others upon the physiological action of chemically unrecognisable quantities of certain substances, especially, for instance, copper, and thought that for this reason the chemical analysis of natural waters afforded, although perhaps the best available, nevertheless not entirely trustworthy data for the artificial manufacture of medicinal waters. Papers were subsequently read by Prof. Marshall, upon the action of heroine and dionine upon the circulation, and by Dr. Dixon, upon the question of injectable purgatives.

An interesting paper upon synthetic purgatives was communicated by Prof. Tunnicliffe. It appears from recent researches into the chemistry of the vegetable purgatives, especially of the rhubarb group, that the active purgative group of these substances is an anthraquinone derivative. Starting from this fact, certain artificial anthraquinone derivatives have been made in the laboratory, and one anthrapurpurin acetate has been introduced into therapeutics as a purgative. This substance is very interesting and marks a decided advance in pharmacology, since it must be regarded as the first synthetic vegetable purgative. According to Prof. Tunnicliffe, however, the phthaleins exert a purgative action, and have certain advantages over both the natural purgatives and also the artificially prepared anthraquinone derivatives. The substance of especial interest in this connection is the chemical indicator phenolphthalein, a dihydroxyphthalophenone. This substance is now to be introduced under the name purgen, and the lecturer gave an account of the results of its administration as a purgative in 1000 cases.

On Thursday the section was devoted to a discussion upon the therapeutic value of arsenic. The discussion was introduced by Dr. Ralph Stockman. The author gave the result of certain observations he had made upon the action of arsenic upon the bone marrow. These researches included microscopical examinations of the bone marrow of patients who had died in the Manchester beer-poisoning epidemic. The discussion was followed by a paper by Prof. Liebreich upon the therapeutic value of cantharidin. In this paper the author discussed the *rôle* played by the capillaries in the absorption and elimination of poisons. He ascribed to each capillary area a specific irritability. Dr. Pope subsequently read a paper upon arsenic in the treatment of chorea.

Friday was occupied by a discussion on the treatment of diphtheria. Subsequently several papers were read of considerable pharmacological interest.

In reviewing the proceedings of the section we may certainly say that it evinced a healthy activity; the material to be dealt with was in excess of the available time. The meetings were well attended by pharmacologists from England, Scotland, Ireland and Wales, and it is certainly to be expected that they will perform the true function of such assemblies and act as a healthy stimulant to further research work in this important subject.

PHOTOGRAPHY OF DIFFRACTION AND POLARISATION EFFECTS.

IT was natural that such a subject as physical optics should call forth the best skill of mechanicians, and science owes a debt to their beautiful instruments; but the very excellence of these has perhaps filled the worker with too much awe and made him feel that wave interference can only be observed in a great laboratory. The present object is to give details of simple arrangements which enable all such phenomena to be seen and photographed.

Diffraction.—The general appearance of the apparatus is shown in Fig. 1. It may be seen at the Victoria and Albert Museum. The middle stand carries a square piece of soft wood blackened, 3 inches square, $\frac{3}{16}$ inch thick, with a $\frac{3}{4}$ inch square cut out of the centre. A dozen or more of these wooden squares should be made, as holders for the various objects which cause diffraction. It is desirable to have some sheet aluminium and rolled brass, the thickness in each case about No. 30 standard wire gauge. Several objects can be made of aluminium and attached with pins to the centre of the wooden squares: a single edge; a rectangular edge for Grimaldi's crested fringes; two straight edges with adjustable distance, the adjusting edge of aluminium being made to slip under two clips of aluminium pinned down, one on either side. The pins should be cut short to about the thickness of the wood; a slight tap with a hammer rivets them. Let three of the 3-inch squares have the central

FIG. 1.

hole covered over with aluminium and let pinholes of various sizes be made; the aluminium is easily cut with scissors and pierced with a needle; when the hole is less than $\frac{1}{5}$ mm. the phenomenon is different from that given by larger holes.

Put thin microscope cover glass on the aperture of two or three wooden squares, and with the smallest speck of liquid glue attach shot of various sizes to the glass. This affords the easiest means of seeing Arago's famous experiment, a bright centre in the shadow of an opaque circular disc.

Other suitable objects are needles of various sizes, needle eyes and needle points. Fig. 2 shows diffraction by a fine and a thick needle. The centre of the shadow is a line of light in both cases; it is the finer needle which has the broader central line. For the same cause the central light broadens towards the points, and the centre of the shadow of a quartz fibre is very broad indeed. On one side of a needle place a strip of aluminium; this causes the interior bands to disappear at this position. To one side of a needle, along half its length, apply a piece of microscope cover glass; this shows Arago's crucial experiment to prove that the velocity is less in glass than in air. It is imperfectly described by saying that the fringes are shifted towards the glass side. There is another system of fringes, narrower and more in number as if from a broader needle; the central line of these is shifted towards the glass. The experiment is rather difficult; the edge of the glass gives trouble; it must be placed just over the thickness of the needle, and the needle had better be thin.

Perforated zinc and wire gauze easily give good effects; the former has series of rings in the spaces, and the centre can be made white or any colour with a small movement of the object;

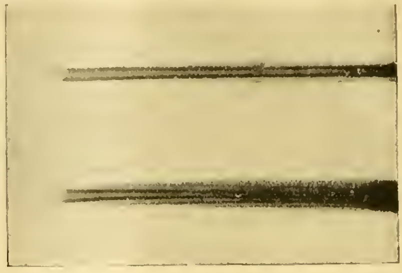


FIG. 2.

also there are fine hexagonal rulings all over the geometrical shadow. The wire gauze gives bright Scotch plaids of any clan, when moved over a range of about two inches.

Some of the most beautiful effects which can be produced are shown in Fig. 3. The diffracting objects were small groups of four and five circles, circular lines of light photographed on glass, each group being $\frac{1}{10}$ inch diameter. They were made years ago for another species of diffraction, that as studied by Fraunhofer, Schwerd and Herschel, in which a telescope is focussed on to a distant point of light and various screens are placed on the object glass. Our present view is that of Fresnel, in which waves starting from a point, almost mathematical, of light are diffracted or broken by an interposing body.

A word more as to the holder of the objects. In the bottom of the 3-inch squares of wood, Fig. 1, is a slot; this slot is placed over a screw fixed in the top of the oblique bar in the middle stand; a nut on the screw clamps the square and allows adjustment in a vertical plane. The lower end of the oblique bar, which is 3 inches long, has a stiff joint on to the upright, which is 9 inches high; the stiff joint makes an easy adjustment for height.

On the left of Fig. 1 is a wooden screen 16 inches high, 9 inches broad. At a height of 10 inches is a hole $\frac{1}{2}$ inch in diameter; on either side of this let there be a brass spring which will allow one of the 3-inch squares to be slipped under it. The square should have a sliding strip of aluminium, with three pin-holes ranging in size from the smallest that can be made. Sometimes an adjustable slit should be placed here. A convex lens condenses lamplight or sunlight on to this aperture, whether pinhole or slit; this is the source of light.

Towards the right hand in Fig. 1 may be seen an eye-piece for

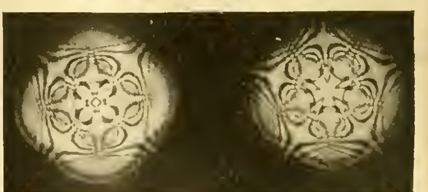

FIG. 3.

direct observation or a camera for photographing the effects. The distance for either of these is about 2 feet from the wooden screen which carries the source of light. The eye-piece is Beck's B microscope Huyghen's eye-piece. Any simple holder

can be made to serve, but it is useful to have a sliding tube in a brass upright and at the top a V which is above a stiff joint. On this V the eye-piece can be held with an elastic band; or an eye-piece of different breadth, or a Nicol's prism may be so fixed. Most of the effects may be well seen if a lamp is used for the source of light. It is easier to observe in a room which is rather dark, for then the space between screen and eye-piece need not be

FIG. 4.

covered up. Sunlight may be reflected by a hand-mirror into a darkroom through an open door. The lens which condenses on to the pinhole can be moved a little until it is seen that a pencil of light is just covering the lens of the eye-piece; then the object can be adjusted so as to be also covered by this pencil. Of course, the effects as seen directly by the eye are far more beautiful than the photographs. The object is about 18 inches from the pinhole. With good sunlight there are often groups of brilliant jewels, in which the emeralds and the rubies are made to change places by a small movement of the object. For producing Arago's bright spot with an object so broad as a threepenny piece, the distance from the pinhole to the eyepiece must be about 36 feet.

In photographing the phenomena the same eye-piece is fitted on to the front of a camera, instead of the usual lens; the camera can be placed on a box and adjusted to the right height with books or paper. If there is good sunlight, about 30 seconds' exposure is suitable for an Ilford ordinary plate. There is no question of focus; to whatever position the back of the camera is drawn out the figures are equally in focus. There is a series of folds or zones of light and shade, and prismatic colours which are often crossing one another and suffering interaction of their waves, so that if these zones are cut at various positions there is infinite change of form and colour. If the same eye-piece is used in a telescope or a microscope it will focus the sun or a diatom on to a screen; and when the screen is moved back the image is still in focus; but in these cases the reason is different, for the pencils of light emerge in parallel rays and make clear images at all positions.

Some of us who are fortunate have been inspired in early life at some well-known school of optics where there was the best

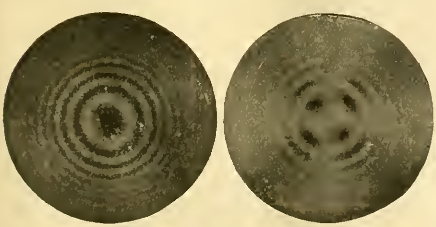

FIG. 5.

teaching and the best instruments; then we descend to our own rough contrivances. There is a third stage, when we watch for examples of wave interference with no apparatus at all. In looking at distant lamps at night-time several forms of Grimaldi's fringes can be seen by moving the eyelids over the eye; with care it is possible to see interference from the light reflected along the eyelashes, and there are fine figures of endless variety which can be produced by slowly lifting the eyelid so as to draw a film of moisture across the eye. Some are similar to the figures of Michelson's refractometer, and all these are probably of the character of thick plates.

Polarisation.—It has often been considered that the rings and brushes made by oblique pencils through crystals can only be seen with elaborate instruments; but according to the method here described all polarisation effects of which the writer has any cognisance have been photographed. It is convenient to cut the cork mounts of the crystals so as to be round, about $\frac{3}{4}$ inch diameter. Place one of these on the top of the same microscope eye-piece, from which the cap has been removed; if the microscope is at hand, it forms a convenient holder. No objective is put on. A Nicol's prism may be inserted at the bottom of the tube. This, however, is not necessary, for the reflection from the plane mirror under the stage polarises almost as well. A cardboard tube, which fits the eye-piece, may be used instead of the microscope. In this case, cut a hole in the side of the tube at the further end and reflect up polarised light by a piece of microscope cover glass fixed on cork with black sealing-wax. A long pin run through the tube and the cork makes easy adjustment for this reflector.

For an analyser a tourmaline is desirable, as light in colour as possible. The artificial tourmalines are best, but they are now difficult to procure. The tourmaline is placed above the crystal section which is already on the top of the eye-piece. Perhaps the cap of the eye-piece will hold these two steady when they are turned to the right position. It is safer to twist thin copper wire round the top of the tube so as to have a small hook on either side; a thin india-rubber band from hook to hook over

FIG. 6.

the tourmaline holds them securely. It is only necessary to place the tube through the front of a camera from which the lens is removed so as to have the figures projected on the photographic plate. Sunlight is best to work with. Sodium light gives a field covered with fine detail, but does not make effective lantern slides.

Fig. 4 shows the calcite cross; Fig. 5 shows calcite circularly polarised and circularly analysed, or circularly polarised and plane analysed. One of the most attractive of polarisation crystals is Bertrand's prism. It is so cut that light entering directly through one side is internally reflected along the optic axis; it then emerges owing to a similar internal reflection. These reflections polarise and analyse; moreover, the first reflection preserves both the ordinary and extraordinary rays. The result is that by placing this one crystal without polariser and analyser on the eye-piece the black-cross and the white-cross systems both appear at once, as seen in Fig. 6. The interest does not end here; with a slight tilt, made by a shaving of cork under one side of the prism, the white and black crosses change places, with certain other changes of detail in the figures; and there is another tilt which will give two white-cross systems.

If Fig. 6 is to be projected on to a screen on a large scale, the crystal is placed at the focus of a convex lens on to which sunlight is turned, or else at the focus made by the condensers of a lantern when the light is drawn back; this is sufficient without a focussing lens. In both cases the heat may injure the crystal unless about $\frac{1}{4}$ inch of water is placed between the lens and the crystal. The ordinary crystals of calcite and nitre must have a Nicol on one side and a tourmaline on the other, and be placed at the focus as before. W. B. CROFT.

THEORY OF THE MOTION OF THE MOON.[1]

DR. BROWN, in the first two parts of his work, has explained his methods. The third part contains little more than tables of results. Our review, therefore, must be necessarily confined to an extension of the tables that have appeared in NATURE on November 25, 1897, and July 13, 1899. It will be seen that the high order of accuracy to which the computations have been pushed has been maintained, and that most of the latest series of terms are very small and, with a few exceptions, below the limits of observation.

HOW THE SABRE-TOOTHED TIGERS KILLED THEIR PREY.

DURING the greater portion of the third or last great geological epoch—the Tertiary period of geologists—there flourished certain very large and powerful members of the cat tribe, commonly known, on account of the inordinate length of their upper tusks, as sabre-toothed tigers, although there is nothing to show that they had any more affinity with the tiger than with the lion. Indeed, they were widely separated structurally from both, as they were from all living cats. In these sabre-tooths the upper tusks were huge, compressed, scimitar-shaped teeth, with the front and back edges generally, if not always, finely serrated. In some of the later species, which existed contemporaneously with man, the upper tusks were eight or nine inches in length, and they were longest of all in a South American species. In the earlier members of the group, before they had attained the inordinate development characterising the later forms, the upper tusks were protected by a descending flange at the fore part of each side of the lower jaw. Apparently, however, this was not found to be a satisfactory working arrangement, and it was accordingly discarded in the later forms, the tusks of which became proportionately thicker so as to stand in need of no such protection. At the same time the whole lower jaw became remarkably slender and weak, so much so, indeed, that it is evident it could not have been used in the same manner as the lower jaw of a lion or a tiger. Confirmation of this view is afforded by the circumstance that the lower jaw articulates with the skull in quite a different way from that which occurs in the last-mentioned animals.

Sabre-tooths were distributed over a great portion of the surface of the globe, their remains having been found in England, France, Germany, Hungary, Greece, Persia, India and North and South America. They lived at first at a time when true cats were either very scarce or entirely unknown, and they appear to have survived longest in South America.

A moment's consideration will show that, at any rate in the case of the longest-tusked species, it was quite impossible for these animals to bite in the ordinary manner, as the entrance to the mouth would be barred by the tusks, which must bave reached to the sides of the lower jaw if the extent of the gape were only equal to that of a lion or a tiger.

This disability has given rise to several suggestions as to the mode in which the sabre-tooths used their upper tusks. One idea was that they were employed as stabbing weapons, and used while the mouth is closed. With the earlier forms, in which the tusks were shorter and protected by a flange on the lower jaw, this method of use would obviously be an impossibility. Moreover, as is pointed out by a writer whose name will be mentioned later on, it would involve, after long adaptation to striking with the mouth open, a sudden change to attacking with the jaw closed. Perhaps a still more serious objection is the fact that the efficient length of the weapon would be diminished by about a half if the attack were made with the jaw shut, and therefore that the animals might just as well have remained in their primitive form, with comparatively short tusks. Again, the closed mouth would obviously be a very serious disadvantage to an animal which drinks the blood of its victims.

Among other strange suggestions, it has been supposed that the tusks were employed as aids in climbing trees! Apart from other considerations, their brittle structure and finely serrated edges would render them obviously unsuited for this purpose. Another idea is that the sabre-tooths were aquatic in their habits, and that their tusks were used in some respects in the same manner as are those of the walrus. Needless to say, this idea, although difficult to disprove in so many words, may be dismissed without serious comment. It may be added that the long tusks of the later and more specialised sabre-tooths have actually been regarded as the cause of the extinction of the group, the idea being that the creatures, owing to the entrance being barred by the tusks, could not open their mouths sufficiently wide to admit food.

Recently, in the *Memoirs* of the American Museum of Natural History, Mr. W. D. Matthew has suggested an explanation of the puzzle, which, although somewhat startling to preconceived ideas, seems on the whole to be the best solution of the problem hitherto offered. Starting with the indisputable fact that the mode of articulation of the lower jaw to the skull is quite different from that which obtains in the true cats, and also bearing in mind the weakness of the lower jaw itself and the smallness of its tusks, the author suggests that the sabre-tooths dropped the lower jaw into a vertical position, and were thus enabled to use their upper tusks as stabbing weapons. An examination of the skull of the large South American species in the British Museum shows that such a position of the lower jaw is quite possible, the small size of its ascending or coronoid branch allowing the necessary movement to be made without interfering with the cheek-arches.

"Presumably," adds the author, "the ligaments were adjusted to these changes, and if so, there appears to be no reason why the sabre-tooth should not open his mouth far wider than is possible for the cat, laying back the chin against the throat without inconvenience. Along with this change there is a decrease in power of the muscles closing the jaw, due probably to lack of use of the lower canines (used against the upper ones in other Carnivora, but useless in this way to the sabre-tooth)."

It is further urged that the disappearance in the long-tusked species of the flange on the lower jaw which protected the canines in the more primitive forms is correlated with this mode of opening the mouth, as the presence of such a flange would prevent the lower jaw lying close against the throat. Moreover, the anterior cheek-teeth, which are used by modern Carnivora chiefly for bone-crushing, and are most developed in the hyænas, have almost disappeared in the sabre-tooths, while, on the other hand, the shearing carnassial teeth—the sole function of which is flesh-cutting—have been inordinately increased in size and power.

As is well known, a large number of the mammalian contemporaries of the earlier sabre-tooths were short-necked and probably thick-skinned ungulates, some of which were more or less distantly allied to the modern tapirs and others to the pigs. And in the same manner as the long-necked and thin-skinned ruminants of to-day form a large portion of the prey of the modern lion, tiger, leopard, &c., so these early ungulates fell victims to the attack of the sabre-tooths. Now, antelope and deer are killed by the neck being bitten through or broken when attacked by the larger Carnivora; but it seems unlikely that such a method of attack would be successful in the case of short-necked and thick-skinned animals.

Accordingly, it is suggested by Mr. Matthew that in the case of the sabre-tooths "their most advantageous method of attack was to inflict stabbing and ripping cuts at points where an artery could be reached, using their short, broad and powerful fore-feet as fulcrums, and probably bleeding the animal to death."

It is added that the earlier appearance of true cats in Europe as compared with North America, where they are very rare throughout the Tertiary period, may very probably be correlated with the earlier appearance and greater abundance of the modern type of specialised ruminants in the Old World. Finally, the largest and most specialised member of the group, the great *Machaerodus neogaeus* of the Pleistocene of South America, which the author believes to have been the slowest mover of its kind, may have preyed on the huge thick-skinned and slow-moving ground-sloths which attained such a remarkable development in that continent. In a subsequent section the author hazards the suggestion that the more cat-like Carnivora known as Dinictis, the upper tusks of which were noticeably shorter than those of the sabre-tooths, were creatures with a greater turn of speed and therefore better adapted for preying on the smaller and swifter-footed Herbivora than was the case with their long-tusked relatives.

R. L.

UNIVERSITIES IN RELATION TO RESEARCH.[1]

IT will perhaps be expedient for me at the outset to say that I propose to use the word research in its widest meaning, *i.e.* as indicating those efforts of the human mind which result in the extension of knowledge, whether such efforts are exerted in the field of literature, of science or of art.

The chief agencies of modern organised research are (1) the learned societies and (2) the universities. The former receive and publish research papers; the latter superintend and direct investigators and publish results. To these should properly be added the various journals which have been established and carried on by private effort. It is a significant fact that the establishment of modern learned societies coincides closely in time with the Renaissance movement. Telesio established one of the earliest mathematico-physical societies—the Academy of Cosenza. Other Italian societies of similar scope were founded in Rome in 1603, in Florence in 1657, and the Royal Society of London dates from 1660 or earlier. Organised research in universities was of slower growth. In them the mediæval spirit was tenacious of life, and it was only in the nineteenth century, in Germany, at the close of the Napoleonic wars, that research, not only in natural philosophy, but in the whole field of knowledge, became the basis of the German educational system, and I might remark, without going into details, that the university systems of France and the other principal countries of Europe, with the exception of Great Britain, are in the main parallel with that of Germany, although not so consistently elaborated.

[1] Abridged from the presidential address delivered by Prof. James Loudon before the Royal Society of Canada at the recent annual meeting of the Society at Toronto.

We are so subject to the authority of words that it is difficult for us to realise that the organisation called a university in Germany is almost entirely different in scope and object from the institution which we so designate in this country. Hitherto, at least in England and Canada, the function of the university has mainly been to impart a general and liberal education, continuing and completing the beginning already made in the secondary school. Speaking generally, I may say that under the German system the work of our secondary schools and universities combined is performed by the gymnasium, the nine or ten years' training of which leaves the young man of nineteen or twenty years of age with a much better liberal education than that possessed by the average graduate in arts of an English, Canadian or American university. How this is accomplished it is not my purpose here to explain. There is no doubt, however, as to the fact, which is substantiated both by the nature of the curriculum of the gymnasium and by the testimony of those familiar with both systems.

It is upon this substantial preliminary training that the work of the German university proper is based. Up to this point the young man has been a "learner"; on entering the university he becomes a "student." This distinction, expressed by the German words "lernen" and "studieren," marks the difference between gymnasium and university—the acquisition of knowledge under the teacher in one, the independent research under the guidance of the professor in the other.

The ultimate object of both professors and students is the advancement of knowledge, and the independence with which research is conducted is well expressed by the two words "Lehrfreiheit" "Lernfreiheit"—the freedom of the professor as to what he teaches and the freedom of the student to select his special line of research. Some idea of the extent of this work may be formed from the number of universities in Germany, twenty-one in all, and from the fact that the aggregate number of matriculated students exceeds 12,000, in addition to non-matriculated students, who are also numbered by thousands, while the philosophical faculty at Berlin and Leipzig in 1901–2 numbered, respectively, 207 and 120. To the twenty-one universities mentioned should be added the nine technische Hochschulen which have now the right to confer the doctor's degree in the applied sciences.

The place and importance of research in the German system is further indicated by the fact that even teachers in the gymnasium devote themselves to such work, their papers being published in the annual reports of their institutions. With such respect is the ability for research regarded that the publication of a paper of this kind may lead directly to a professorship in the university, as was the case, for instance, in the appointment of Weierstrass, the celebrated mathematician.

In the organisation of the German university, research has been shown to be a fundamental principle; in the British university it is as yet incidental or of sporadic manifestation. I do not, of course, ignore the very important contributions which have been made by British scholars to the advancement of learning, but it is worthy of note that the credit for their splendid achievements is rather due to the individuals themselves than to the universities with which many of them were connected. The British university is not primarily an institution for research. In its function of providing the higher grades of a liberal education the proper comparison is with the upper classes of the German gymnasium, not with the German university proper. True, we find in some of the British universities a specialisation in certain subjects, *e.g.* in honour classics and mathematics at Oxford and Cambridge, leading to higher work than that attempted in the gymnasium; but however advanced the studies may be, there is rarely any attempt to guide the English undergraduate in the direction of research. Reading and examinations are the academic watchwords, and to the great mass of students and tutors the field of research is a *terra incognita*.

The attitude of the British nation has been hitherto largely that of indifference towards organised research, and this has been true, not only of the general public, but also of those engaged in academic administration. There has existed a deep-seated conviction, born perhaps of reiterated assertion, that the British university system is superior to that of Germany or any other country, and as near perfection as may well be. We are not concerned just here with the discussion of the merits of the system, which are undoubtedly many and great, but we must admit that the attitude of self-satisfaction which has prevailed, combined with the ignoring of other ideals, is at least unphilosophic. In the

midst of such an atmosphere it is not surprising that the development of a true Renaissance spirit has been somewhat tardy.

But the British nation is on the eve of an awakening, an awakening which has already taken place among certain leaders of thought. The fact is dawning upon the British mind that some vital connection really does exist between national progress and scientific discovery, and that the latter should be fostered in connection with the higher institutions of learning. Under the conviction that British commercial supremacy will be seriously threatened unless foreign, and especially German, scientific methods are adopted, universities of a more modern type than Oxford and Cambridge, and also technical colleges, have been established. Such institutions no doubt fill a long-felt want, but they do not go to the root of the matter. On the academic side they are but a modification of the older type; on the technical side they contemplate, not the discovery of new truth, but the application of what is already known. The spirit of research is lacking, and without it no expenditure of money, no raising of examination standards for mere acquirement, will actually increase the capital account of national knowledge.

The policy of the universities of the United States regarding this matter is in marked contrast with the indecision and conservatism which prevail in the mother country. The type of mind which has been developed in the century and a quarter of separate national existence is one of great vigour and originality; but these qualities have for the most part been turned aside by the circumstances of a new country from abstract investigations. Research after the almighty dollar by the nearest short-cut has been, and perhaps still is, regarded as the chief national characteristic of our American cousins, and in this pursuit they have displayed a genius for concrete research in mechanical invention and an ability for commercial and industrial enterprise which have been an object of wonder, and latterly of anxiety, to other nations. During the first hundred years of national existence the university of the gymnasium type which had been inherited from England continued to develop and expand in the United States. Suddenly, however, almost exactly twenty-five years ago, a remarkable modification was introduced.

Since 1877 many universities, including the best of those already in operation, as well as new foundations, have added a graduate department leading to the Ph.D. degree, although none of these, with the exception of Clark University, has made the prosecution of research the sole business of the university. Some idea of the rapid progress of this movement may be gathered from the fact that the numbers pursuing graduate studies in the universities of the United States have increased from 8 in 1850 to 399 in 1875, and to about 6000 in 1902.

I have confined my remarks up to this point almost wholly to the historical aspect of the question, but it will perhaps not be out of place for me to point out in conclusion some of the advantages which in my opinion are connected with the pursuit of university research.

Let us consider first the stimulating effect upon the individuals and institutions concerned. Among those who are affected by this stimulus should first be named the professor. Dr. Samuel Johnson was wont to compare accumulated knowledge to a heap of ice lying exposed to the summer sun, the bulk of which could not be maintained without constant replenishment. Continuing the figure, we can readily imagine that the professor's fund of knowledge which is ample enough for the class-room teaching of immature minds might shrink and trickle away until little is left but the sawdust which we usually associate with the preservation of that commodity. Under the stimulus of research this is impossible, for research into the new implies a full and minute mastery of that branch of knowledge in which the research is being conducted Hence if no other advantage resulted a good case might be made out along this line of argument.

This stimulus to the professor would react with increased force upon the student. It was a favourite saying of a certain celebrated artist that those who follow after others rarely outstrip them. To hold up before the student either by theory or practice solely the ideal of acquiring what has already been learned is mediævalism pure and simple; it is to teach him to creep where he might walk upright and alone; it is to rob him in part of that intellectual birthright of independent thought which is the inheritance of every man, at least since the Renaissance. It is sometimes objected that the results attained by research students are often trivial or futile. I am disposed, however, to agree with a remark made by one of George Eliot's characters:—"Failure after long perseverance is much grander (and I would say parenthetically more useful) than never to have a striving good enough to be called a failure." It is sometimes also urged that research in the immature student leads to superficiality and conceit. I cannot but think this fear ill-grounded. It has been proved, on the contrary, that nothing will so quickly ripen and enlarge preliminary knowledge and so effectually extinguish presumption as the hand-to-hand struggle with some special problem in the department of study in which the student is already proficient.

Apart from the professor and student, the first effect of the inauguration of research work in our universities, if of the genuine stamp, will be felt upon the teaching profession of the country as a whole. Assuming an educated and interested public opinion, the premium so long placed upon memorised knowledge will disappear, and a change in the principle of selection of teachers both in universities and secondary schools will result.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

AFTER consultation with Mr. Astor, and in accordance with his wish, the council of University College, London, has resolved to endow the chair of pure mathematics and to name it the "Astor chair." The staff of the reorganised department of chemistry of the College will be as follows:—General and inorganic chemistry: professor, Sir William Ramsay, K.C.B., F.R.S.; assistant professors: Dr. F. G. Donnan, Dr. Morris Travers and Mr. E. C. C. Baly. Organic chemistry: professor, Dr. J. Norman Collie, F.R.S.; assistant professor, Dr. S. Smiles.

THE Royal Commissioners for the Exhibition of 1851 have made the following appointments to science research scholarships for the year 1902, on the recommendation of the authorities of the several universities and colleges:—University of Edinburgh, J. K. H. Inglis; University of Glasgow, A. Wood; University of St. Andrews, W. Wallace; University of Aberdeen, A. C. Michie; University of Birmingham, J. A. Lloyd; Yorkshire College, Leeds, H. D. Dakin; University College, Liverpool, F. Rogers; University College, London, E. P. Harrison; Owens College, Manchester, G. C. Simpson; Durham College of Science, Newcastle-on-Tyne, C. R. Dow; University College, Sheffield, G. B. Waterhouse; Queen's College, Galway, W. Goodwin; University of Toronto, W. C. Bray; Dalhousie College, Halifax, Nova Scotia, T. C. Hebb; University of Melbourne, R. Hosking; University of Adelaide, W. T. Cooke; University of New Zealand, M. A. Hunter. The following scholars nominated in 1901 have had their scholarships continued for a second year on receipt of a satisfactory report of work done during the first year:—F. Horton, A. Slator, R. B. Denison, G. Owen, G. Senter, F. W. Rixon, T. Baker, S. C. Laws, Alice E. Smith, J. Hawthorne, R. K. McClung, C. W. Dickson, G. Harker. The following scholars nominated in 1900 have had their scholarships exceptionally renewed for a third year:—Dr. W. M. Varley, Dr. S. Smiles, J. A. Cunningham, W. S. Mills, J. Patterson, J. Barnes.

THE Cambridge summer meeting organised by the Local Examinations and Lectures Syndicate was opened on Friday last with an address by the vice-chancellor, Dr. A. W. Ward, master of Peterhouse. Many men of distinction are taking part in the meeting, and the lectures cover a very wide range. The general subject of the meeting is "Some Aspects of Life and Thought in Europe and America in the Nineteenth Century." In the section of physical and natural sciences, the following lectures will be delivered during the meeting, which is divided into two parts, and ends on August 26:—"Some Modern Astronomical Speculations," Prof. G. H. Darwin, F.R.S.; "Sidereal Astronomy," Mr. Arthur Berry; "Meteorology in the Nineteenth Century," Dr. W. N. Shaw, F.R.S.; "Pasteur and his Work," Prof. Sims Woodhead; "An Aspect of the Influence of America on Geology," Dr. R. D. Roberts; "Progress of Geology in the Nineteenth Century as illustrated by modern views on (1) The Structure of the Earth's Crust, (2) The Evolution of the Configuration of the Surface," Mr. J. E. Marr, F.R.S; "Advances of Botany," Prof. H. Marshall Ward, F.R.S.; "A Great Botanist: Sachs," Prof. W. B. Bottomley; "Colour Photography," Mr. T. B. Wood; "The Rise and Development of Electro-Chemistry," Mr. D. J. Carnegie. Among the subjects in the section of education are:—"Hygiene as a Factor in National Education," Miss A. Ravenhill; "Nature-Study" (Six Lectures), Prof. Patrick Geddes;

and "Illustrative Lectures in Nature-Study," Miss Von Wyss. There will be practical courses in nature-study (chemistry and botany) and in geography in its physical aspects. A conference upon the subject "In what sense can and ought Schools (Primary and Secondary) to prepare Boys and Girls for Life?" was opened by Dr. M. E. Sadler on Saturday last, and one on "Hygiene in Schools" will be opened by Miss Ravenhill on August 14.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 28.—M. Bouquet de la Grye in the chair.—On a curious property of a class of algebraic surfaces, by M. Emile Picard.—Reflection and refraction by a body transparent undergoing a rapid translation; equations of motion and some general consequences, by M. J. Boussinesq.—The reduction of nitro-derivatives by the method of direct hydrogenation in contact with finely divided metals, by MM. Paul Sabatier and J. B. Senderens. Nitronaphthalene is readily reduced to naphthylamine by hydrogen in presence of reduced copper at 350° C. With nickel the reduction goes further, ammonia and naphthalene tetrahydride being formed. Nitromethane and nitroethane are reduced completely to the corresponding amines.—A method of spectrum analysis capable of furnishing the still unknown law of rotation of planets of feeble brightness. Verification of the method, with preliminary results, by M. H. Deslandres. This method, which was applied with success in 1895 to the measurement of the rotation of the bright planets, has now been extended to those of lesser magnitude, including Uranus and Neptune.—The entire image of the planet submitted to spectrum analysis undergoes deformations from which the sense of the rotation can be determined, and to a certain extent its velocity. The rotation of Uranus has been found to be retrograde.—On the problem of Dirichlet for domains limited by several contours or surfaces, by M. A. Korn.—On one of the causes of the explosion of steam boilers and on a means of preventing it, by M. J. Fournier. It is shown that with the ordinary form of safety valve the release may take place in the normal way, and yet an insufficient amount of steam may escape to prevent the pressure rising to a dangerous extent. A modification of the ordinary safety valve is described in which this difficulty is overcome.—On magnetic dichroism, by M. Quirino Majorana. Active liquids behave in a magnetic field like uniaxial crystals possessing dichroism.—On the electrochemical equivalent of silver, by M. A. Leduc. A short account of researches the complete description of which will be published shortly in the *Journal de Physique*, in which the effect of temperature changes, current density, and acidity of the bath upon the value of the electrochemical equivalent of silver has been determined.—The silvering of glass and daguerreotype, by M. Izarn. A minute description of the method of silvering glass by means of ammoniacal silver nitrate and solutions of formaldehyde.—On the precipitation of the chlorides and bromides of cadmium, mercury and tin by sulphuric acid, by M. Georges Viard.—On mannite, the nitrates and the alkaloids of normal urine, by M. S. Dombrowski. By applying the method of separation described in a previous note the author has succeeded in isolating from urine sodium nitrate, cadaverine, mannite and a new alkaloid.—An attempt at an immediate analysis of nerve-tissue, by M. N. Alberto Barbieri.—On the ligature of the appendicular extremity of the cæcum in *Cercopithecus cephus*, by M. Jean Maumus.—The internal secretion of the testicle in the embryo and in the adult, by M. Gustave Loisel.—The microbial kinases; their action on the digestive power of the pancreatic juice together with albumin, by M. C. Delezenne.—The parasitic nature of certain calcareous degenerations, of some inflammatory tumours and of special lesions of the skeleton, by MM. A. Charrin and G. Delamare.—A comparative study of hæmatolysis by poisons in the dog and rabbit, by M. C. Phisalix.—On a new form of tactile sensibility, trichesthesia, by MM. N. Vaschide and P. Rousseau.—On the possibility of combating mildew and oidium of the vine by a liquid treatment, by M. J. Guillon.—On a method of concentrating wine, by MM. Baudoin and Schribaux. The method which was found to give the best practical results consisted in first partially distilling the wine at a low temperature and then removing some water from the distillate by freezing.—The prehistoric drawings in the grotto of La Mouthe, Dordogne, by M. Emile Riviere. Facsimiles of drawings of a reindeer and of a horse are given.

NEW SOUTH WALES.

Royal Society, June 4.—Prof. Warren, president, in the chair.—The parks of Sydney; some of the problems of control and management, by Mr. J. H. Maiden.—A possible connection between volcanic eruption and sunspot phenomena, by Mr. H. I. Jensen. The author of this paper mentions that the idea of the existence of such a connection was suggested to him by the fact that Vesuvius was in violent eruption in the years 1813, 1822, 1855, 1867, 1891 and 1900, all of which were minimum years. By means of a chart he shows that earthquakes and eruptions are most violent, numerous and extensive when there is least sunspot activity. Though seismic disturbances do occur at all times, they seem for the last hundred and twenty years to have been most severe around the minimum years—1811, 1822, 1833-4, 1844, 1855-6, 1867-8, 1878-9, 1888-9 and 1900-2—large groups of great earthquakes and eruptions having taken place in and about these years. On the other hand, the chart also shows that in years of maximum, like 1893-8, 1884-5, 1869-71, 1858-65, and so on, these phenomena have been comparatively few and unimportant. The author thinks that the cause of this connection between solar and seismic disturbances is that in years of sunspot minimum there is less heat, and other energy, received from the sun, and consequently there is more rapid radiation from the earth, causing quicker cooling, hence more cracking of the earth's crust. He also suggests that the earth's atmosphere exerts a greater squeeze on the crust in years of minimum, thus forcing lava out of fissures.

THE ENCYCLOPÆDIA BRITANNICA.

The Encyclopædia Britannica. The Third of the New Volumes, being vol. xxvii. of the Complete Work. Chi–Eld. Pp. xx + 744. (London : A. and C. Black, and *The Times*, 1902.)

IT is impossible within the limits of a short notice to describe even briefly more than a few of the scientific articles in this new volume of the "Encyclopædia Britannica." Many subjects of interest to men of science are dealt with, the following being among the contributions :—Cholera, Dr. A. Shadwell ; chronograph, Rev. F. J. Jervis-Smith ; biblical chronology, Prof. S. R. Driver and Mr. C. H. Turner ; coal, Mr. H. Bauerman ; Cœlentera, Dr. G. H. Fowler ; colours of animals, Prof. E. B. Poulton, F.R.S. ; combinatorial analysis, Major P. A. MacMahon, F.R.S. ; comets, Dr. E. S. Holden ; compass, Captain E. W. Creak ; condensation of gases, Prof. J. D. van der Waals ; conduction of heat, Prof. H. L. Callendar, F.R.S. ; copper, Dr. J. Douglas ; cremation, Sir Henry Thompson, Bart. ; Crustacea, Rev. T. R. R. Stebbing, F.R.S. ; Ctenophora, Dr. G. H. Fowler ; cuttlefish, Rev. J. F. Blake ; cytology, Mr. Harold W. T. Wager ; dairy, Dr. W. Fream ; Darwin, Prof. E. B. Poulton, F.R.S. ; dietetics, Dr. W. O. Atwater ; differential equations, Mr. H. F. Baker, F.R.S. ; diffraction gratings, the late Prof. H. A. Rowland ; diffusion of gases, Prof. G. H. Bryan, F.R.S. ; dimensions of units, Dr. J. Larmor, F.R.S. ; diphtheria, Dr. A. Shadwell ; du Bois-Reymond, Sir Michael Foster, K.C.B., F.R.S. ; dyeing, Prof. J. J. Hummel ; dynamo, Mr. C. C. Hawkins ; analytical dynamics, Prof. Horace Lamb, F.R.S. ; dynamometer, Prof. W. E. Dalby ; figure of the earth, M. R. Radau ; earthquakes, Prof. J. Milne, F.R.S. ; Echinodermata, Dr. F. A. Bather ; Echiuroidea, Mr. A. E. Shipley ; eclipse, Prof. Simon Newcomb ; economic entomology, Prof. F. V. Theobald ; education, Sir Joshua Fitch and Dr. N. M. Butler ; eel, Mr. J. T. Cunningham ; Egypt (physical geography), Major H. G. Lyons ; and Egyptology, Prof. W. M. Flinders Petrie, F.R.S., and Mr. F. Ll. Griffith ; and elastic systems, Prof. A. E. H. Love, F.R.S.

It will be evident from this selected list of subjects and authors that science is well represented in the volume, and that the editors have endeavoured to secure authoritative statements of the position of knowledge of many departments of scientific study. In general, the articles contain good accounts of advances in the departments of intellectual activity with which the writers deal, but there are some in which the view described is not so comprehensive as it might have been.

Take, for instance, the article on eclipse, which is supposed to bring the information up to the present position of knowledge of the subject as regards eclipses of the sun. We find various details referring to the extent and structure of the corona, and the number of lines photographed during various eclipses, but there is no clear view of the subject as a whole. Significant observations are overlooked, while others are catalogued without any attempt at analysis of the material. The article on comets is just as unsatisfactory, and the only value it has to a student of the subject lies in the catalogues of elements of these bodies. Nothing is said about such important points as the distribution of orbits, the origin of comets or their spectroscopic history.

The article on education, by Sir J. G. Fitch, is worthy of the "Encyclopædia." Its main purpose is

"to trace the gradual growth of what may be called the English system, the forces which have controlled it, and the results it effected during the last quarter of the nineteenth century."

For purposes of comparison, a brief account is also given of the provision made for education in three or four nations of Europe in which the people are less hampered by tradition and the leaders are animated by a progressive spirit. Towards the close of his valuable paper, Sir Joshua Fitch points out some of the problems of the future.

"The motive force which we need," he remarks, "must be found in a higher and truer popular conception of a liberal education, and of its relation to the formation of character and to the duties of industrial, civic and family life. That the acquisition of knowledge, though obviously the prominent business of a school, is not the whole of education, and that knowledge consciously directed to the special professional and industrial needs of life is of far less real value than the knowledge which helps to bring out the best powers of the reflective and accomplished man, are truths which are yet imperfectly recognised."

The scientific study of Egyptian antiquities is reviewed in the article "Egyptology" by Prof. W. M. Flinders Petrie and Mr. F. Ll. Griffith. The latter confines his attention to the ancient language.

Egyptology is a science in the making, and as yet no general scientific systems of Egyptian archæological or linguistic study which command the allegiance of all Egyptologists have been worked out, although in the archæological field great progress has been made in this direction, owing chiefly to the work of Prof. Petrie. Any general article dealing with Egyptological study must, therefore, be in great measure a statement of personal opinion on the subject. So in these two articles by Messrs. Petrie and Griffith we have not so much general reviews of Egyptian archæological and linguistic study as *ex-cathedrâ* statements of the opinions held by two distinguished Egyptologists. These, however, are stated without any hint being given to the reader that many other equally distinguished Egyptologists disagree with them. For instance, Prof. Petrie's whole reconstruction of the first two Egyptian dynasties, based on the results of his excavations at Abydos, has recently been challenged in almost every point by Prof. Naville, the distinguished Egyptologist of Geneva, in the *Recueil de Travaux.*

Now we do not think that the Genevan professor's challenge is by any means altogether successful, but the fact that it could be made at all is a proof of the uncertainty of the whole matter. But no hint of uncertainty is given by Prof. Petrie on pp. 720, 722 of the "Encyclopædia" where he deals with it.[1] Similarly, the description of the

[1] Prof. Petrie's article was no doubt already set up in type before the publication of that of Prof. Naville, but this makes no difference to the argument ; the uncertainty existed from the first.

language given by Mr. Griffith on pp. 726–731, while it contains much matter on which all scholars are agreed, and have been agreed since the time of De Rougé, nay, since the time of Champollion, is, in the main, as he himself makes quite clear, a statement of the views of a particular school of German Egyptologists, led by Dr. Erman, to which Mr. Griffith has attached himself.

Now, leaving English Egyptologists out of account, we find that these views are more or less shared by Prof. Sethe, Prof. Steindorff, Prof. Spiegelberg, Prof. Breasted, Dr. Schäfer, and a few others of less note. They are not only not shared, but are constantly criticised, by Prof. Maspero, Prof. Naville and Prof. Piehl, while Profs. Wiedemann, Lieblein and Schiaparelli, MM. Revillout, Lefébure and others, have not shown the slightest disposition to accept them. In England, Prof. Petrie himself has, so far as we are aware, never yet signified his adhesion to the views which Mr. Griffith expounds. Certainly Prof. Petrie never uses the hideous transliteration of the hieroglyphs, without conventional vowels, which is the shibboleth of the Berlin school. Mr. Griffith does, and he is justified in using it in scientific work, but we regret his use of it in a popular encyclopædia, for no person ignorant of the hieroglyphs can possibly comprehend it, and words written according to its rules cannot be pronounced without the insertion of the necessary conventional vowels, which might just as well be inserted in print. Mr. Griffith uses a transcription which is intelligible to the layman in the publications of the Egypt Exploration Fund; why not in the "Encyclopædia Britannica"?

Scientific opinion is therefore sharply divided on the subject of the language, and, this being so, we are of opinion that Mr. Griffith should not have stated the Ermanian theory without giving his readers any hint of the existence of this division of opinion.

Prof. Petrie's historical summary is, after the debatable period of the earliest dynasties is passed, naturally no longer so much an exposition of his own personal views, although on one or two points (*e.g.* the date of the Antef kings) he seems to differ from the opinion of the majority nowadays. His section dealing with archæology generally is of great interest and value. Fig. 10, giving the principal types of Egyptian pottery from the early predynastic period to the twenty-sixth dynasty, is very appropriate to an encyclopædia.

The existence of differences of opinion on important matters among Egyptologists in no way points to any condition of chaos in Egyptology; on the contrary, it rather indicates the energy and vigour of the study, to the furtherance of which men like Prof. Naville and Prof. Maspero are, no less than Prof. Erman, Prof. Petrie and Mr. Griffith, devoting the best energies of their lives.

In Prof. Driver's article on "Old Testament Chronology," which is, generally speaking, very learned and comprehensive, we have one fault to find. At the beginning of the chronological table (p. 77), the professor, after giving Ussher's date for the Creation, proceeds in a most absurd manner to give the "probable real date" for the creation of man, which date, he opines, is "indeterminable, but much before 7000 B.C." (!) Why 7000 B.C. in particular? Because, in the column "Events in Contemporary History" (*sic*), given parallel to the Creation, we find under "Babylonia" the statement "7–6000. Temple of Bel at Nippur founded." So that the Creation Week must have been in a year somewhat anterior to the foundation of the Temple of Bel. Indubitably, but surely in the present year of grace this sort of thing is somewhat ridiculous, and worthier of a theological text-book for the use of Boer predikants (who are credited with also believing that the world is flat and that the sun goes round it) than of the "Encyclopædia Britannica!"

The article on "Earthquakes" contains some valuable sections. Within the compass of two and a half pages, we have accounts of most of the best instruments that have been constructed for the registration of earthquakes, whether of near or of very distant origin. These should be read in conjunction with the article on "Seismometers" in the ninth edition, which as yet is far from obsolete. Following the section referred to are paragraphs in which the results obtained from instrumental records are pithily described, those on velocity being an admirable summary of the important work of recent years. The practical applications of seismometry in the regulations to be observed by builders and engineers in earthquake countries will be read with no less interest than profit. These are all subjects on which the writer of the article is a recognised authority. Other branches of the science are treated in less detail. The sections on the origin and on the frequency and periodicity of earthquakes are hardly representative of our present knowledge on these subjects. Nor are there more than bare allusions to seismic sea waves, earthquake sounds and the changes of surface features produced by earthquakes. In particular, we miss a consecutive account of the phenomena of a typical earthquake. The progress of seismology, however, has been so rapid since the issue of the corresponding article in the ninth edition that to treat all branches in their due proportion within the limits of eight pages would be a difficult task and one requiring very extensive reading.

With the exception of the article "Dynamo," by Mr. C. C. Hawkins, the volume does not contain much of special interest to the electrical engineer. The article on the "Compass," by Captain E. W. Creak, is a useful addition to that in the ninth edition, and that on "Copper" contains a brief summary of the growth and importance of the electrolytic refining industry.

Mr. Hawkins's contribution deserves fuller mention, not only on account of its intrinsic merit, but because it fills a gap more keenly felt, since the references to the dynamo in the ninth edition are very meagre. The present article, however, brings the subject quite up to date. It opens with a brief discussion of the general theory of the induction of electric currents and an account of the development of a practical machine from Faraday's revolving copper disc. The different methods of field and armature winding for continuous-current machines and alternators are then considered more in detail, but not too elaborately. A general summary of the leading types of machine and a consideration of the suitability of each for different classes of work are also given. As a whole, the article forms a valuable contribution to the literature of the subject, and, without going into the matter very deeply, gives an interesting survey of the

present position of the dynamo from both a theoretical and a practical point of view.

The first of the more important biological articles included in the volume is one on Cœlentera, by Dr. G. H. Fowler, in which it is shown how much our conception of this group has altered since the date of the previous issue. The colours of animals are treated of by Prof. E. B. Poulton, who lays emphasis on the advance of our knowledge with regard to the object of the general coloration of mammals and birds. Crustacea are described by the Rev. T. R. Stebbing, Ctenophora by Dr. Fowler, and cuttlefish by the Rev. J. F. Blake. In the genealogical table accompanying the latter article it is noticeable that Octopus (or rather Polypus) is regarded as the descendant of an ammonite of the Hoplites group, and also that the author accepts the view of one or two German writers as to the homology of the argonaut shell with that of an ammonite. The Echinodermata (called Echinoderma in the table of contents) are elaborately treated by Dr. F. A. Bather, while Mr. A. E. Shipley is responsible for that small marine group known as Echiurids, and, from the presence of segmentation in larval life, sometimes classed as Annelids.

The very important subject of economic insects falls to the lot of Prof. F. V. Theobald, but limitations of space render his article all too short. Recent investigations into the breeding-habits of the eel and the discovery of the real nature of "leptocephali" have enabled Mr. J. T. Cunningham to render the article "Eel" one of especial interest. The only botanical subject is cytology (vegetable), for which Mr. H. W. T. Wager is responsible.

ASPECTS OF MEDICAL SCIENCE.

Pathologie générale et expérimentale. Les Processus généraux. Par A. Chantemesse and W. W. Podwyssotsky. Pp. xiv + 428; 162 figures. (Paris: G. Naud, 1901.)

Matière médicale zoologique, Histoire des Drogues d'Origine animale. Par H. Beauregard, Professeur à l'École supérieure de Pharmacie de Paris. Revisé par M. Coutière, with a preface by M. D'Arsonval. Pp. xxxi + 396; numerous plates and illustrations. (Paris: G. Naud, 1901.) Price fr. 12.

Chemische und medicinische Untersuchungen. Festschrift zur des sechzigsten Geburtstages von Max Jaffé. Pp. 472; 7 plates. (Braunschweig: Vieweg u. Sohn, 1901.)

Das Wirbeltierblut in mikrokristallographischer Hinricht. Von Dr. med. H. U. Kobert. Mit einem Vorworte von Prof. R. Kobert. Pp. 108; 26 figures. (Stuttgart: Ferdinand Enke, 1901.)

THE first book before us is the first volume of a system of general and experimental pathology. In an academically written preface of ten pages, the authors explain the object of the book, pointing out the extreme value of comparative experimental pathology in elucidating the prime problems of morbid processes in the human subject. In especial the authors cite the work of Pasteur on silkworm parasites, and that also of Metchnikoff on the effects of irritants upon low forms of life. Equally well might the recent researches upon the causation of malaria have found a mention in this connection. M. Chantemesse's Russian collaborator, M. Podwyssotsky, has already published in Russian a general experimental pathology covering similar ground to the volume under consideration. The present work, however, is much more extensive, both with regard to the letterpress and figures, and can in no sense be regarded as a translation from the Russian.

It is impossible in a short review to enter adequately into the subject-matter of so compendious a volume, and little more than a table of contents can be given. More than half the space is devoted to the degenerations, which are treated very fully, each having appended to it a copious, we were going to say appalling, bibliography. These huge lists of papers bearing on the corresponding subject are really the more appalling in that upon glancing through them it at once becomes evident that they are more complete with regard to French and Russian workers than with regard to German and English ones. Judging from them and the text, it appears that the authors are not well acquainted with current English scientific literature, as the number of English authors quoted is very small, and the same cannot be said of the English work done upon the subject in question. Certainly one, and in the reviewer's opinion not the least, of the advantages of the book is that it makes accessible to a cosmopolitan public a mass of Russian work, evidently of great value, which otherwise, on account either of its language or its inaccessibility, might have easily escaped the observation of workers in the field of experimental pathology, to their and their readers' detriment.

Under the degenerations are included goitre and cretinism, the authors giving, concerning these affections, an interesting series of experiments upon the effect of the water of the district upon endemic goitre. Saint Jean de Maurienne is apparently one of the most goitrous districts of France, and the waters here have actually the reputation of producing goitre, and are resorted to with success by certain individuals anxious to avoid compulsory military service. Glycosuria is discussed under glycogenic degeneration. An interesting section is devoted to watery and vacuolar degeneration, which includes a detailed description, with very beautiful illustrations, of the vacuolisation of the cells of the central nervous system under the influence of certain toxins and drugs.

The book throughout is written in a most lucid and attractive style, and in a distinctly philosophical manner. The amount of subject-matter treated is very great, and even subjects having little more than an indirect bearing upon the main theme of the book are exhaustively discussed. Some idea of the extent to which this is done may perhaps be formed in noting that no less than fifty pages are devoted to the subject of heredity, and that under this division of their subject the authors include a lengthy discussion of the views of Weissmann. The subject of argyrosis, or general pigmentation following the administration of silver salts, occupies six pages, and has appended to it a copious bibliography.

The reviewer regrets that the references in the bibliographies are not numbered, even when quoted in the text; reference to any given paper is by this fact

rendered very difficult. This difficulty is exaggerated since the position of any given name in the bibliography quoted in the text is not determined alphabetically, but by the date of the corresponding paper. This chronological arrangement of the bibliographies may possibly render them more valuable as entities, but certainly renders them more unwieldy for the purpose of their true function, viz. their reference to the text.

The volume is exceedingly well printed and provided amply with illustrations, often of preparations made by the authors, the execution of which leaves little to be desired. The book will certainly rank as a standard work of reference, and if the high efficiency of the present volume be maintained by its successors will certainly be accorded an emphatic welcome by all pathologists. The authors and the publishers are distinctly to be congratulated upon what can only be the result of labour at once skilful and unremitting.

The second work under notice is a posthumous one. As all interested in pharmacy in France know, M. Beauregard died some months before the publication of his "Matière médicale zoologique." Up to the very last, however, he took the keenest interest in it, and it is pathetic to note from the introduction that the proof sheets were corrected by the author upon the sick bed from which he was never to rise. The author is well known for his researches upon pharmaceutical subjects; these have, further, been in large measure directed to products of animal origin. Especially should his work upon the animal vesicants and upon the animal perfumes find mention here.

The volume which is the object of this review is a compendious book of reference upon all substances used, not only in pharmacy, but also in perfumery, which owe their origin to the animal kingdom. It must be at once observed that the information in the book is for the most part zoological, and that the chemistry of the products in question is not entered into at all fully. In many instances there is little to be said from the chemical side, but it is well to remark that from the chemical standpoint the book cannot be considered as comprising all that is known. Cod liver oil and musk are to some extent exceptions. Under cod liver oil the author gives an account of Gautier's work on the alkaloids contained in this substance, but no mention is made of Hegerdahl's researches on the chemical composition of the fatty constituents of the oil. Under musk an interesting paragraph is added upon artificial musks; nine synthetic substances, mostly butyltoluene derivatives, are mentioned which approach more or less closely to musk in smell. These substances, however, all differ from the natural musk (the preputial secretion from a variety of reindeer) in being less lasting. The extraordinary way in which musk keeps its smell renders this substance very valuable. The trade in this commodity is considerable, and in France is certainly increasing; in 1895, 686 catties (604 grammes) were imported into France and 465 into London. At the present time musk fetches about 100*l*. a kilogramme.

Amongst other substances which are treated very exhaustively from the zoological side may be mentioned spermaceti, the crystalline fat derived from the head of the sperm whale, and the rare substance ambergris. The literature of ambergris is very small, and M. Beauregard has certainly added very considerably to it. It appears that this interesting substance is an intestinal concretion occurring in certain whales. Ambergris is not employed in medicine, but is very much prized in perfumery on account of the property it possesses, although itself odourless, of reinforcing the scent of other substances. The chief market for ambergris is apparently at Boston, and some idea of its value may be formed from the fact that it sometimes fetches as much as 28*l*. the kilogramme.

The vesicant insects, *Cantharis vesicatoria* and its immediate allies, are, as was to be expected, treated very fully. The book concludes with a chapter devoted to the sponges.

From the above somewhat disjointed review it will be seen that M. Beauregard has for his last work produced a valuable addition to the literature of a subject concerning which not much has been written. We are afraid the limited number of readers to which the book will appeal will render the sale of it relatively small; be this as it may, the gratitude of those interested in the subject is due to the author for having collected in a most readable volume the scattered work of many observers, among which must be mentioned his own.

The German custom of celebrating the birthdays of professors by publishing a collection of papers by their collaborators and pupils has many advantages. The collection of monographs published to celebrate the sixtieth birthday of Prof. Max Jaffé by his former collaborators and pupils, although not quite so compendious as many of its forerunners, nevertheless contains an interesting collection of papers. The subject-matter may roughly be divided into three parts. The first series of papers is chiefly devoted to clinical medicine, and is written, for the most part, by old collaborators of Prof. Jaffé who have become famous as clinicians. Amongst these may be mentioned Prof. Leyden, who contributes an article upon the therapeutics of oxygen, and Prof. Nothnagel, from whose pen comes a most useful essay upon intestinal hæmorrhage.

The second series of papers, the shortest in the book, comprises three essays upon pathological, morbid anatomical and embryological subjects.

The third part of the book, occupying more than half its entire bulk, is essentially experimental. The first essay seems to be an entirely chemical one. Dr. Salkowski contributes an article upon the chemical composition of hydrocephalus fluid; he draws attention to the fact that the fluid is different in acute and chronic cases in so far as concerns its content of potash salts. He regards the excess in potash salts of acute hydrocephalus fluid as due to the fever which accompanies the acute variety. Normal urine contains, according to this author, only 21 per cent. of the sum of potash and soda salts as potash salts, whereas in fever urine 87 per cent. of this sum consists of potash salts.

An interesting piece of work by Dr. Rudolf Cohn, on the glycocol-store of the organism, comes from the Laboratory of Experimental Pharmacology and Medical Chemistry at Königsberg. It is a contribution to the study of intermediate tissue change. The work consists essentially of a repetition, by other methods, of that of Hugo

Wiener. The fact that benzoic acid is converted by the organism into hippuric acid, and is poisonous only in so far as it is not so converted, is made use of to estimate the quantity of glycocol present in the organism under different conditions at any given time. The result of the researches, in the author's opinion, shows that in rabbits the store of glycocol is neither small nor constant, and that it bears a constant relationship to proteid katabolism; further, that this relationship appears to be the same whether the proteid material be katabolised in the animal body or by external chemical means.

Prof. Hans Meyer, conjointly with Dr. J. T. Halsey and Dr. F. Ransom, contributes a paper on tetanus. The stimulus to this research appears to have been the work of Courmont and Doyon upon the influence of temperature upon the development of tetanus after the injection of the tetanus toxin. The results of Meyer and his collaborators are in the main confirmatory of those of the earlier observers, and appear to show distinctly that cold has a marked preventive influence upon the development of tetanus in animals after the injection of tetanus toxin. These results point, according to Ehrlich and his school, to the fact that the "toxophore" group, in the case of tetanus, develops slowly, and only at relatively high temperatures. The nearest poison of known chemical composition to the tetanus toxin is strychnine, and Koeninck has shown that the development of the symptoms of strychnine poisoning in animals is independent of the temperature.

The book contains other interesting essays, which the space at our command does not permit us to review.

Dr. Kobert's pamphlet is intended primarily for those interested in the medico-legal detection of blood, and consists for the most part of a compilation of the facts at present known upon this subject, culled from the appropriate original works. In some respects, however, it is original, especially with regard to the description and figure of hæmochromogen crystals, and hence will in this sense be possibly of use to physiological chemists generally. The book apparently owes its origin to a practical course upon the detection of blood stains which Prof. Kobert gave himself, and which in a much less complete form appeared in *Zeitschrift für angewandte Mikroscopie*.

The first few pages of the monograph are devoted to the interesting subject of the mutuality of iron and copper with regard to the blood pigment. It is a known fact that in certain invertebrata the blood performs its respiratory function through a copper compound. This physiological equivalence of copper and iron in this respect is distinctly of interest in connection with the supposed toxic effect of copper.

A considerable space is devoted to the interesting substance hæmatoporphyrin, which occurs in human urine especially after the administration of sulphonal, a very commonly used hypnotic. The relation of hæmopyrrol (methyl propyl pyrrol) to hæmoglobin and chlorophyll is also discussed in the light of the work of Marchlewski and Schunck.

A short section is devoted to blood serum crystals, and the pamphlet concludes with a concise bibliographical and general index.

The booklet is certainly thoroughly written, and will be found useful by those especially interested in this somewhat limited field, as well as of practical use in guiding the medical jurist with regard to method.

F. W. T.

CHEMICAL ESSAYS.

Essays in Historical Chemistry. By T. E. Thorpe, C.B., LL.D., F.R.S. Pp. xii + 582. (London: Macmillan and Co., Ltd., 1902.) Price 12*s.* net.

IT is always a pleasure to read any of Dr. Thorpe's essays; in this volume a number of them, delivered on very different occasions, at intervals during the last twenty-five years, have been collected. Some have been published in book form before, but several, which are to be found in the present work, are reprinted from NATURE and from the *Transactions* of the Chemical Society.

The first essay—that on Robert Boyle, "the father of modern chemistry"—displays Dr. Thorpe's admirable style at its best. One is struck by the great wealth of allusion to contemporary events, touched lightly, it is true, but none the less giving a clear impression of the times in which the subject of the essay lived, and of the surroundings in which he carried on his work. Dr. Thorpe possesses, too, a happy knack of apt quotation; the particular passage from a writer of prose or poetry which best illustrates the point which he wishes to make flows easily from his pen, and gives much interest and spice to his narratives. The essay on Boyle is a sketch; much that is interesting is omitted, and there is plenty of room for other essays on Boyle; but what is told is written in such an attractive style, and gives such a perfect picture of the quiet, meditative philosopher—*philarethes*, or the friend of virtue, as he calls himself in a passage which might with advantage have been quoted—that to complain of a lack of completeness would be to appear to undervalue what is given.

Dr. Priestley is the subject of the next sketch. Again the same careful delineation of character is to be noted; but perhaps in the life of Scheele, the subject of the third essay, Dr. Thorpe is at his best. It is hardly fair, however, to the shades of Mayow to credit Dr. Priestley with the invention of the pneumatic trough, although the name, doubtless, is due to him; for Mayow's *Tractatus quinque* contain many illustrations of that convenient appliance.

In the essay on Cavendish, a delightful picture is given of an imaginary soirée at the house of Sir Joseph Banks:—

"The portly visitor, with the large frill, makes his way upstairs, to the evident embarrassment of a thin middle-aged gentleman in an old-fashioned Court-dress of faded violet, and a knocker-tailed periwig, who is moving uneasily about on the landing, evidently afraid to face the assembly. The approach of the gentleman on the stairs, however, drives him into the room. He shuffles quickly from place to place, his manner is awkward; his face betrays a nervous irritation of mind, and he appears annoyed if looked at. It is the Honourable Mr. Cavendish. Finding himself close to a group, evidently, from the appearance which their faces wear, speaking of a deeply important matter, he draws near to listen. They are talking of a rumour of some grave disaster which has befallen my Lord Cornwallis and his troops, who it

would seem have been circumvented in some unexpected manner by the machinations of that arch-rebel Washington. Mr. Cavendish is scarcely interested, and he moves aside to catch something concerning, it may be, some fresh eccentricity of poor Lord George Gordon, or perhaps some account of the troubles of the unhappy Mr. Watt, the engineer, who, it is said, is fighting tooth and nail to defend his just rights from a set of unprincipled rogues who pirate his inventions. None of these matters is sufficiently moving to detain him. But his manner quickly alters when he overhears the mention of the name of Mr. Herschel. Mr. Herschel is a musician at Bath, who employs his leisure in constructing big telescopes, with one of which he has just discovered a new planet. Mr. Cavendish is greatly interested; he listens with marked attention; he is even about to put a question, and begins in a nervous, hesitating manner, and in a thin, shrill voice, when his eye catches that of a stranger; he is instantly silent, and retires in great haste, for he has a horror of a strange face. The portly gentleman with the large frill espies him, and comes up with a foreign gentleman, who is formally introduced to Mr. Cavendish. Mr. Cavendish is assured by the portly gentleman that his foreign friend is particularly anxious to make the acquaintance of a philosopher so profound and so universally celebrated—all of which is confirmed by the foreign gentleman, who adds that it was, indeed, his chief reason for coming to London, that he might see and converse with one of the most illustrious philosophers of that or any other age. Mr. Cavendish is speechless; he is overwhelmed with confusion, until seeing an opening in the crowd, he darts through it with all possible speed, and reaching his carriage, is driven home."

This it must be acknowledged is a most graphic piece of descriptive narration; it conveys the man and the age like a living picture. The author would have made a thrilling novel-writer, at all events on the descriptive side.

The sketch of Lavoisier, although giving a fair account of his life and works, possibly treats at too great a length of his tragic death; but this error (if it be one) is partly atoned for in the next essay, in which the rights (and wrongs) of the dispute regarding the share of Priestley, Cavendish and Lavoisier in the discovery of the nature of combustion and of the composition of water are fully discussed. No English chemist will dispute that while Priestley and Cavendish, personally, and through Blagden, furnished Lavoisier with the facts relating to the preparation of oxygen and the composition of water, it was Lavoisier who interpreted them correctly. It is strange that Priestley (in a passage quoted on p. 153) and Cavendish, in his paper in the *Phil. Trans.* for 1784, p. 150, both consider the advantages and disadvantages of using the conceptions given to the world by Lavoisier; and both, after stating arguments on both sides, prefer the method of statement in terms of phlogiston. It is a pity that such international disputes should arise; would that scientific men of all nations would take to heart the words of Pasteur:—

"I find myself deeply impressed by two propositions: first, that science is of no nationality; and secondly, in apparent but only apparent contradiction, that science is the highest personification of nationality. Science has no nationality, because knowledge is the patrimony of humanity, the torch which gives light to the world. Science should be the highest personification of nationality, because, of all nations, that one will be the foremost which shall be the first to progress by exerting thought and intelligence. Let us strive, for strife is effort, strife is life, when progress is the goal."

The strife should consist in trying to raise one's own nation to the highest pinnacle of intellectual and industrial greatness, and not in disputes as to priority of discovery and invention.

A full analysis is given of Graham's work, and his biography is pleasant reading. The genial, kindly nature of the man is well brought out. The remaining essays, on Wöhler and Liebig, founded on Hoffmann's charming biography; of Kopp and of Victor Meyer, both old friends; and of Mendeléeff and Cannizzaro, enter more into the details of their chemical work, and may therefore prove of less interest to the general reader; but they are fairly exhaustive, and produce the effect which they were intended to produce—a high estimate of the genius and hard work of the subjects of biography.

The progress of chemistry in this country during the nineteenth century was the subject of Dr. Thorpe's presidential address to the Chemical Society in 1900; it is conceived in his best style, and presents a life-like picture of the progress of the science in the early part of the century. A continuation of this sketch is promised, but up to now has not appeared. But it is acknowledged to be easier to paint a distant landscape than a near one; the numberless details, which produce somewhat of confusion when close, merge into broad masses of colour when sufficiently far away.

One conclusion, among many, stands out conspicuous from Dr. Thorpe's pages. It is the enormous influence of the teacher on the taught; how potent is the effect of personal contact with the experienced investigator on the future career of the young student! Scheele with Retzius and Bergmann, Watt with Black, Lavoisier with Rouelle, Faraday with Davy, Graham with Thomson, Wöhler with Gmelin and Berzelius, Liebig with Gay-Lussac, Dumas with De Saussure and De Candolle, Kopp with Gmelin, Victor Meyer with Bunsen. It is rare that a young man has, like Boyle and Cavendish, sufficient initiative and perseverance to forge a way for himself. As Prof. von Baeyer once remarked to the writer of this notice:—"I care not what a young man knows; if he can only *think*, after he has left my laboratory, I feel that I have done my duty by him." When will this elementary view of education influence the action of those who legislate on the training of our youth? W. R.

AN ASSISTANT MASTER, AND HIS WORK.

The Schoolmaster: a Commentary upon the Aims and Methods of an Assistant Master in a Public School. By Arthur Christopher Benson, of Eton College. Pp. vi + 173. (London: John Murray, 1902.) Price 5*s.* net.

THIS book is not, and does not profess to be, a manual of pedagogy. The reader in search of help in regard to school organisation, to the allocation of time and subjects, to the methods of teaching generally, the bearing of Herbartian or other philosophical theories on practical problems, or educational politics in any sense, will probably find the book disappointing. The author has little or nothing to say on the relation of

Government or public authorities to the school and its teachers, the influence of external examinations, the place of science in the curriculum of a school, the professional training of school masters, or any of the numerous subjects which form the staple of newspaper controversy or Royal Commissioners' reports in relation to school policy and work. His point of view is simply that of a classical master, whose work has been done only with scholars drawn from the upper ranks of society, whose educational ideals have been formed by Eton traditions and by the requirements of the universities, and who discusses with his readers in an informal and conversational fashion the question how, under the exceptional conditions of a boarding-house at a great public school, the utmost can be done to foster manliness, good scholarship and the characteristics of a Christian gentleman.

But within this limited range of observation and experience Mr. Benson has acquired much valuable knowledge, and his book shows him to be distinguished, not only by literary skill, but also by a genuine love for his profession and by a keen and sympathetic insight into the nature and the needs of boyhood. His view of the spiritual and mental relationship which should be established between a wise teacher and his pupil, his large tolerance for differences in the character and tastes, the virtues and the faults of boys, his belief in Thring's well-known *dictum* that there is no such thing in the world as a good-for-nothing boy, and his insistence on the value of an atmosphere of cheerfulness and intelligence as distinguished from the mere learning of lessons —all give a special charm to the book and will serve to make it peculiarly attractive to young teachers who are not pedants, but who seek to achieve the highest and truest kind of professional success.

The discussion on the prospects of the teaching profession and its disadvantages is marked by much candour :

"No enthusiasm will ever quite succeed in gilding a trade which consists in part of providing food and lodging for a large number of people and charging them rather more than they cost."

On the other hand, to one who is drawn to the profession by a sense of personal fitness and by a liking for the work,

"there is a certain attractiveness about the perpetual exercise of minute control, there is a sense very strong in the British character of pleasure in exercising discipline and showing power"; "there is no profession which is so apt, if exercised faithfully, sympathetically and tenderly, to broaden the character and enlarge the spirit,"

and it often happens that the man who begins as the careless, self-regarding practitioner of a not very dignified

"trade discovers that he is in the thick of a very real and vivid life which stirs all sorts of interests and emotions and brings home to him some of the deep realities of life."

The writer of such passages is under no illusions and has no temptation to magnify his office unduly; but he is deeply impressed with its seriousness, and he believes that a young teacher will find, as he acquires new power and stronger sympathy, increased delight in his work. As to specific training for that work, Mr. Benson is somewhat sceptical. Apparently he is not speaking from any experience of trained as compared with untrained colleagues : but because his own success has been attained by other means than formal preparation, he pronounces boldly that training can never make a man an effective teacher. He thinks that

"a sensible man may learn more in a week from teaching a division of his own when he has no one to depend on but himself than in months spent in a training college."

His plan appears to be to treat a class of boys as the *corpus vile* on whom pedagogic experiments may be tried, and he adds with charming *naiveté*,

"As far as mere methods are concerned, I am sure I could tell a young man in half an hour the simple dodges which have proved in my own case useful and effective."

The author fails to see that while a man endowed with natural gifts such as insight into character and professional enthusiasm may become a valuable teacher without training, it is evident that the rank and file of the teaching profession will find themselves at least helped by some knowledge of the philosophy of the art they profess and by some acquaintance with the methods and performances of famous teachers, and of the reasons for their success or failure.

The best chapters in the book are those in which the author discusses the means by which school lessons may be made interesting and attractive to boys.

"A school lesson," he says, "should be of the nature of a dramatic performance from which some interest and amusement may be expected, while at the same time there must be solid and business-like work done. The aim ought not to be to turn everybody into a literary personage. Literature is only one province of the intellectual life. . . . An intellectual person is one whose mind is alive to ideas, who is interested in politics, religion, science, history, literature, who knows enough to wish to know more and to listen if he cannot talk."

But no man is capable of generating in his pupils a real love for knowledge unless he himself cultivates some intellectual interests apart from the obvious routine of school work.

"The master, out of school, should live in the company of good books and big ideas. Everyone cannot be interested in everything, but everyone is capable of being interested in something, and I do not care very much what the subject is, provided only that there is a little glow, a little enthusiasm in it."

On the well-worn topics of athletics, on holidays, on prizes, on the right use of chapel services and on moral teaching, Mr. Benson speaks with strong conviction and good sense. His aims are high, but he is afraid to set up impossible ideals or to forget that, while temptation is often strong and boys are weak, they

"are in their better moments earnestly and pathetically desirous to be kept from evil, and that no help which the schoolmaster can give them is ever thrown away."

The book abounds with obvious truisms, but they are rendered attractive by the freshness with which they are stated, and by the fact that they are the product of actual experience and of the serious devotion of a life to

duties which the author has learned to enjoy as well as to fulfil. In the midst of much that he and others regard as revolutionary in educational theory, and of many importunate claims on the part of "modern subjects" in schools, it is useful for us all to be reminded, as in this book, of what may be done in connection with the traditional discipline of the great public schools, when the work is undertaken by men who, though standing honestly *super vias antiquas* in regard to the staple of school teaching, are nevertheless profoundly conscious of the needs of our own time, and who look on scholarship, not as an end in itself, but mainly as a means to the higher end of Christian manhood and honourable citizenship.

OUR BOOK SHELF.

The Dictionary of Photography. By E. J. Wall, F.R.P.S. Revised and brought up to date by T. Bolas, F.C.S., F.I.C. 8th edition. Pp. iv + 656. (London: Hazell, Watson and Viney, Ltd., 1902.) Price 7*s.* 6*d.* net.

THE fact that the eighth edition of this dictionary is now published is the best of all evidence of the appreciation that it continues to receive. And this appreciation is deserved, whether one regards the work of the author or the reviser. So far as we have been able to examine the work, the information it gives is sound and useful. Mr. Bolas states that he has added nearly a hundred new pages of subject-matter, as many fresh headings and many new diagrams, but by a process of concentration and elimination has not increased the bulk of the volume so far as to render it unwieldy.

The great difficulty in compiling a book that aims at being something more than a simple guide for beginners and something more handy and less costly than a treatise that aims at approximate completeness, is to satisfactorily apportion the available space to the various subjects. As the needs of no two readers are exactly alike, a very wide margin must be allowed for the discretion of the compiler, but we notice a few cases in which the reviser might with advantage have extended his work of adding to the original, even if it necessitated still more "concentration and elimination." The page and a third devoted to "amphitype," for example, might well have been spared, while the six or seven lines devoted to "hypo-eliminators" might profitably have been expanded to a couple of pages. The getting rid of sodium hyposulphite is a problem that has to be attended to in the production of every negative and silver print, and even if all "eliminators" are regarded as useless, some are still on the market, and every thinking photographer wants to know something as to their mode of action, advantages and drawbacks.

Acetylene is very unfairly treated. After it has been in use for so many years as it has, and has proved to be so convenient, effective and safe, it must be a prejudiced view of it that leads to its consideration in less than a page, half of which is devoted to its endothermic and consequently supposed dangerous character, and the other half to its history and a statement that the "great hopes" concerning it have not been realised!

In the selected bibliography of photography some hundred and twenty books are mentioned, ranging from apparatus makers' pamphlets and beginners' guides to the most comprehensive works; but of the few books recommended for students by the City and Guilds examiners, presumably because of their educational value, we have counted nine in English, including three on general photography, that are not mentioned. This difference can hardly be dismissed as due to the exercise of a wise discretion.

These are examples of the cases in which the reviser might have gone even further than he has in his additions, concentrations and eliminations. Doubtless he will do so when the next edition is called for.

Die Entwicklung des Gesichtes: Tafeln zur Entwicklungsgeschichte der aeusseren Koerperform der Wirbelthiere. By Carl Rabl. Part i., *Das Gesicht der Saeugethiere.* With 8 plates. (Leipzig: Engelmann, 1902.) Price 12*s.*

THIS, the first of four parts of a comprehensive work, deals with the development of the external form of the head-region in rabbit, pig and human embryo. How many different vertebrate animals the author proposes to make use of for the purposes of the research is not stated, but it may be recognised that the net is cast widely enough when within its meshes so lowly an animal as the lamprey is to be contained. The figures of the eight folio plates, drawn by the author, are certainly exquisite, quite unique, indeed, of their kind. From others previcusly published they differ in two important respects. While the former rarely exceed a magnification of five diameters, the present ones possess three times this, and —a very important point—they are the first series of the kind to be lithographed by the firm of Werner and Winter. This is a sufficient guarantee that full justice has been done to the originals by the lithographer's art.

In fundamental features the drawings, perhaps, hardly reveal anything not already visible in the well-known pictures of pig and human embryos published by His and Keibel. Possibly novelties may be looked for in subsequent parts of the work. To the figures extant of normal human embryos, those here given will form additions welcome to the anatomist and the embryologist alike. As to the others, the one noticeable deficiency is that they stop short of and do not at all cover the period when, for instance, the pig-embryo first becomes unmistakably a member of the genus Sus, a representative of the species *Sus scrofa*, and a pig with a particular individuality of its own. That is to say, the author ignores what His has termed the period of the passage of the embryo into the fœtus, the point when the unfolding of the embryo is about finished.

The work, which with so large a number of fine plates is remarkably cheap, is being published by the aid of the Imperial Academy of Sciences, Vienna.

Les Fleurs du Midi. By P. Granger. Pp. viii + 371. (Paris: J. B. Baillière et Fils, 1902.)

THE vast quantity of early flowers which reaches this country in the early spring from the Mediterranean region might lead one to suppose that the conditions of the climate there are entirely favourable to the forcing and rapid development of plants. A perusal of this book indicates that the gardeners of the littoral do not find circumstances by any means so propitious, for the east wind causes drooping of the leaves and withering of the flowers, while the mistral coming from the north-west at times blows with such force that trees are uprooted and shelters overthrown.

The various protective devices, whether hedges or trees, glass frames, straw mats, &c., are fully described and illustrated, together with the conditions under which they may advantageously be employed. Then follows a discussion of various details, such as manures, insecticides, the best methods of gathering and packing, and the cost of freight. The main bulk of the book treats of the plants which lend themselves to cultivation during the winter, with an enumeration of species and varieties which are suitable to the climate and likely to yield a remunerative return for time and money expended in their production. The book is essentially practical and represents the outcome of several years' experience. The

type is good and the illustrations form an important feature, being artistic and at the same time expressive and useful.

Physiology for Beginners. By Leonard Hill, M.B., F.R.S. Pp. viii + 124. (London: Edward Arnold, 1902.) Price 1*s.*

IN this tiny volume the author has set himself the difficult task, as he describes it in his preface, of putting in simple language the essential facts concerning the structure and functions of the human body.

The book is intended for junior students who have no previous knowledge of the subject, and it may be said that the author has put forward the main essentials of the subject in an attractive way such as ought to engage the interest of school children, for whom the book is obviously intended. The author clothes his subject in the homeliest possible phraseology, avoiding technical terms and hard names so far as can be done in dealing with such an abstruse subject, and instead of giving dull definitions he suggests and then answers questions which must arouse interest in the juvenile mind.

Although mainly written for use as an elementary school book, the volume may be recommended to anyone who wishes to obtain some knowledge of the functions of the different organs of the body without the trouble of a detailed or technical study of the subject.

The book is artistically got up and adorned with many clear and well-drawn illustrations of the subject-matter.

B. MOORE.

Die Philosophie August Comte's. By L. Lévy-Brühl. German translation by H. Molenaar. Pp. 286. (Leipzig: Dürr'schen Buchhandlung, 1902.) Price Mk. 6.

THIS is a careful translation into German of a full and sympathetic study of Comte's positivist philosophy in all its aspects. M. Lévy-Bruhl is not one of those more cautious disciples who, like Littré, rejected Comte's religion in the name of his philosophy. He boldly defends the whole later development with its curious substitute for Catholicism as a necessary consequence of the original Comtian conception of a reform of society operating by means of a reform of philosophy. The actual subject of his book is, however, the philosophy apart from the subsequent developments. He treats with lucidity and knowledge in his first book of the foundations of the positivist doctrine, the alleged "law of the three stages," the classification of the sciences and the concept of law. In books ii. and iii. he presents a sketch of the natural and social sciences, exhibiting their interrelation. The concluding book is devoted to an exposition of the positivist ethics. The translation reads well and pleasantly, and makes one wish that we in England, where Comte is more talked about than studied, possessed a statement of his doctrine at once so lucid and so concise.

A. E. T.

Elementary Coal Mining. By George L. Kerr. Pp. 225. (London: Charles Griffin and Co., Ltd. 1902.) Price 3*s.* 6*d.*

THIS volume "is meant as an introductory manual to the larger and more advanced text-books." The subject-matter is dealt with in fourteen chapters, at the end of each of which there are examination questions. The information is given concisely and in a form adapted for easy assimilation by students preparing for the examinations held under the Education Department and the County Councils and under the Home Office for under-managers' certificates. There is no striking novelty in arrangement or in the matter dealt with. The 200 illustrations are good and clear. Several of them appear to have been borrowed from Mr. Herbert W. Hughes's well-known text-book, with no mention of the source.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Earthquake of May 28 at the Cape, and Coincident Meteorological Effects.

As certain peculiar meteorological phenomena seem to have been closely associated with the earthquake felt in the Cape Peninsula on May 28, the following particulars of this occurrence seem to deserve notice.

After being practically calm all day, a loud sound resembling a clap of thunder or the rumbling of approaching heavy waggons was heard about 11.45 p.m. (Cape mean time of $22\frac{1}{2}°$ east), followed in Cape Town and Green Point by a heavy downpour of rain, and in the suburbs by a severe squall of wind and rain; practically simultaneous with the sound there occurred a shaking and rattling of windows and doors; some state they felt also a distinct shock, others that their beds rocked, while information was received of the cracking of the walls of at least two dwelling houses. The wind-squall was strong enough to uproot or blow down trees in some of the eastern suburbs. One gentleman, whose written account is in our possession, states that "it fairly shook the room and its contents which I occupy at Rosebank; shortly afterwards a similar sound (tremor?) was felt; it lasted only a few seconds and died away." Dogs were apparently conscious of the occurrence, one which was never known to be affected by thunder or lightning moving about and whining in a peculiar manner, while a parrot indicated by its screeching that it was sensible of something unusual happening.

Our meteorological records show that rain fell (except on May 19) every day from May 17 to May 24, amounting to 3·10 inches at the Royal Observatory and to 7·45 inches at Newlands. Between the 24th and 28th, although no rain fell, there was almost an entire absence of drying winds, being chiefly light from the N.W., from which direction comes the bulk of the Cape Peninsula rainfall.

Barometric pressure was high[1], 30·071 inches at 8 a.m. on May 27, but fell steadily to 29·775 inches at 6 p.m. on May 28, after which it remained stationary, so far as hourly eye-readings showed, until 11 p.m.; between 11 p.m. and midnight it fell to 29·717 inches, and rose rapidly to 29·771 inches at 12.15 a.m. on May 29, to 29·809 inches at 12.25 a.m., and to 29·817 at 12.30 a.m., unusually large and rapid fluctuations for the Cape Peninsula, and suggesting at once the presence of thunderstorms in the neighbourhood. These rapid variations in pressure might account for the rumbling sound, on the supposition of it being thunder, also for the wind-squall, and even for the rattling of doors and windows (not affected by ordinary winds), but fails to account for the "rocking" of the beds, the cracking of walls and the unusual behaviour of the dog already mentioned, all these inducing the belief that an actual "earthquake" was experienced.

No record of any seismic disturbance was, however, shown on the seismometer at the Royal Observatory.

The lightkeeper at Cape Point makes these remarks on his meteorological schedule for May:—"28th: wind S.E. to S.W., light; silent lightning from N. to N.W. at 8 p.m., then thick fog from 10.30 p.m., and a light drizzling shower at 11.45 p.m. Fog and rain till midnight, then thunder and lightning at midnight; again rain off and on from 1.40 a.m. till 8 a.m. on May 29."

Through the courtesy of Mr. D. E. Hutchins, Conservator o. Forests, the writer has been enabled to examine his barogram obtained at Cape Town for the period between Tuesday, May 27, and Sunday, June 1. This record shows a dip in the curve occurring after 11 p.m. on May 28. Similar irregularities are recorded for the early mornings of May 29 and 31; these too were associated with thunderstorms, but may be connected with the West Indian eruptions of about the same date, an account of which is given in your issue of June 5.

In the absence of fuller information than is in our possession at present, no definite connection can be traced, but these phenomena seem to be closely related one to the other. At least, it will be admitted that a comparison of this barographic curve with the diary of events in the West Indies shows some

[1] Corrected to 32° Fahr., but not to sea-level; approximate height of barometer, 40 feet.

most peculiar coincidences :—(1) Renewal of eruption of Mont Pelée on morning of May 28 ; peculiar atmospheric disturbance at the Cape, simultaneous with earthquake shock there. (2) Renewal of irregularities in pressure curve on May 29 and 31 and early morning of June 1, there being renewed volcanic disturbances in West Indies on or about these same dates. The curve for these last two days is remarkable, resembling closely a series of ripples and suggesting "interference" effects.

Which was cause and which effect, or is there any correlation whatever ? CHARLES STEWART.

Meteorological Commission, Cape Town, July 16.

A Tripartite Stroke of Lightning.

AT about 6.50 p.m. on August 7, after two or three preliminary low thunder rumblings, which by no means prepared us for what was to come, a most tremendous crash of combined thunder, lightning and electric discharge burst right over my residence here.

My butler, who was looking in the direction of our front gate, 80 yards to the north of our front door, saw a burst of smoke, mingled with a shower of leaves, rise into the air out of the adjoining shrubbery.

My coachman, who was sitting just within the open door of the lodge, close to the front gate, was dazed by a vivid burst of flame at his feet which seemed to leap into the doorway.

My neighbour's gardener, looking out of the lodge opposite, saw a nearly horizontal flash of fire enter the shrubbery close to my front gate.

A subsequent examination of the surroundings of the front gate and my coachman's lodge has revealed :—

(1) A tearing up of the ground close to the massive iron post of the front gate, the splitting of a large flint at its foot, and a litter of ivy leaves on the gravel.

(2) The clean cutting in two of an oak post, 35 yards distant to the north-east, from which an iron hand-gate was hanging.

(3) The scorching of the outside foliage of a horse-chestnut some 15 yards still further off, in a direct line with the other two objects struck.

In thirty years' experience of thunderstorms, which are rather frequent here, I have never observed the simultaneous striking of three different points by the electric discharge. A death-like stillness succeeded the crash, the storm appearing to have exhausted itself in a single tremendous explosion. Heavy rain was falling when the crash occurred. I have measured an inch and a half of rain-fall within the last three days.

Six Mile Bottom, Cambs., August 8. W. H. HALL.

Colours between Clouds at Sunset.

ABOUT sunset on the evening of Sunday, July 13, being at Ripon with my son, our attention was arrested by an unusual appearance, which I will briefly describe. Two large clouds, covering a considerable portion of the western sky, and separated by an interval leading generally towards the west, were each bordered along this interval by a bright and well-marked double spectrum. The two spectra forming this were together of the width of about one and a half times the diameter of the sun ; they followed the foldings of the edge of the clouds, and, which suggests a partial explanation, were at right angles to a fringe of nebulous striæ, which bordered the clouds, so that, except that the spectral colours were parallel instead of consecutive, the phenomenon had in some degree the appearance of the reflection from a grating.

Our observation lasted about twenty minutes, and it was especially noticeable that when, through the fading light, the more refrangible colours had disappeared, the two red lines on the rim of each cloud remained clearly marked to the last.

Never having previously seen or even heard of such an appearance, any information on the subject would be much appreciated. I might also report that on the evening of July 17 the pink streamers mentioned by some of your correspondents could be well observed, and had they been less stable, and had they radiated from the north instead of from the position of the setting sun, the appearance would have much resembled the Aurora Borealis. JOHN BADDELEY.

Adswood, Bury New Road, Higher Broughton, Manchester.

Retention of Leaves by Deciduous Trees.

ONE of the proofs in favour of this being caused by early frost is that frequently on exposed beech and other deciduous trees only the leaves near the ground are affected and remain brown on the trees until the spring. Leaves higher up escape the frost and fall normally, as these early frosts are usually confined to the strata of air near the ground. W. R. FISHER.

Coopers Hill, Englefield Green, Surrey, August 8.

THE WEST INDIAN ERUPTIONS.

AMONGST the last contributions to our knowledge of the eruptions which so recently devastated portions of the West Indies are five preliminary reports to the National Geographic Society. These, with excellent illustrations, appear in the July magazine of the Society.

In the following notes upon these reports attention is drawn to those portions of their contents which are not generally known, and to these are added a few observations made by witnesses, particularly those made by Captain E. W. Freeman, of the s.s. *Roddam*, whose experiences, although he was interviewed by members of the American expedition, have as yet received but slight consideration.

The first report is by Mr. Robert T. Hill, of the U.S. Geological Survey, who, with other scientific investigators, accompanied a relief expedition in the U.S. steamer *Dixie*, which sailed from Brooklyn Dock on May 14.

Notwithstanding the ill-advised introduction of matters foreign to the object of a scientific expedition, the bulk of Mr. Hill's report is well worth consideration. La Montagne Pelée, which has been introduced to our notice as the goddess of Hawaii and as the mountain which is bare or "naked," is now referred to as the "shovelfull," an allusion possibly to its form. In May, 1901, we are told that a picnic party discovered on its summit a small fume rising at one corner of its crater lake. On April 23 three distinct shocks were felt in St. Pierre, and everybody saw a great cloud of smoke rising from the summit crater. Two days later the lower Soufrière was in eruption, and from this date until May 5 the showers of ashes steadily increased. The succeeding sequence of events has already been published in these columns, whilst the observations of April 23 bring us nearer to the seismic disturbances of April 19, which, although they originated in Central America, there are strong reasons to suspect were the primary cause of disturbances in the Antillean fold.

As the introduction to the account of the catastrophe Mr. Hill mentions his witnesses, and here we find for the first and last time in these reports the name of Captain Freeman. Certainly there is a reference to his vessel. According to engineer Evans, of the *Roraima*, which was burned, the *Roddam* was lifted on a wave "so that her anchor chain broke and she was enabled to escape," which is not correct. Now at the time the great and fatal blast swept across St. Pierre and its roadstead, Captain Freeman was on the deck of his vessel—then about three ships' lengths from the shore—and for some time at least could see what occurred, whilst other witnesses whose testimony is referred to had sought refuge in engine-rooms or down below. Captain Freeman says that although there were many minor puffs of clouds from Pelée there was only *one* great eruption, and this came from the side of the mountain. There were no detonations or loud reports, and from his point of view there was no sheet of flame accompanying or following the blast. The force of this, which came with the wind, was so great that he believes it was the cause of the s.s. *Grapler* turning turtle. There was no return blast, neither was there any absence of air. The difficulty in breathing was due to the quantity of fine ash with which the atmosphere was charged and the fetid gases with which it was mixed.

The *Roddam* was not saved by being lifted on a wave, neither was it saved by knocking out shackle pins and slipping the cables. What Freeman did was to free his windlass and then run full speed astern until the cable parted. After that, the steering gear being jammed with ash, he steamed ahead and then astern, close to burning ships, seeing and hearing the cries of those on board and also of those who were running to and fro along the shore. From this it is certain that many of the people in St. Pierre did not die suddenly. Twenty-six of his own men also died, and for the most part they died slowly. At the end of an hour and a half the gear was cleared and he escaped. Then came a shower, not of mud, but of rain. About eight hours later, with 120 tons of fine sand-like ash upon its deck, the *Roddam* steamed into St. Lucia. Notwithstanding the fact that possibly 2 or 3 per cent. of this material consisted of grains of magnetite, and the quantity of ash containing this material above and around his vessel was so great that daylight was replaced by a darkness that could be felt, such compasses as were left in the *Roddam* were serviceable for navigation and did not show any irregularity in behaviour. Before the eruption nothing unusual was observed in the barometer.

These few notes, which bear upon the reports we are considering, but, as will be seen, are not entirely in harmony with the same, come from a man who saw the great explosion, was in the midst of its blast and saw what could be seen from the sea of the events which closely followed its occurrence.

That Captain Freeman, whilst on a burning ship, where he was more than half suffocated with hot ashes, when the boots were burned from his feet, his face seared and his hands so scorched and welted that he worked with his elbows, had the presence of mind to do what he did and the physical and mental power to carry out his intentions under these trying conditions is one of those instances of will-power and endurance possessed by few so well worthy of record. Let it be repeated, the *Roddam* was not saved by accident, but it was saved as Captain Freeman saved it once before whilst eleven other steamers foundered, by good judgment and courage, and it is to be hoped that before long he will receive from underwriters or others substantial recognition, not only for his services on the *Roddam*, but for the example he has placed before the world.

To return to Mr. Hill's report, at 7 o'clock on the morning of May 8 Mr. Ferdinand Clerc observed the needle of a large aneroid barometer pulsating violently, and it was in consequence of this fact that he left the city and escaped. It is, of course, possible that these movements were due to the air disturbances accompanying the outbursts of "smoke" which preceded the great eruption. This eruption, which took the form of a big black cloud, no doubt made up of ash, steam and other gases, issued from "a point fully 1000 metres below the summit" and travelled at the rate of a mile a minute downwards over the surface of the earth upon St. Pierre and its harbour. The ashes which fell upon the deck of the *Roddam* were found still to be warm thirteen days after the eruption.

At the time they fell on the *Roraima* they were hot enough to ignite rope and bedding, but not to ignite wood. This statement, according to Captain Freeman, means that the level surface of a deck would not be fired by a thick layer of such ashes, whilst woodwork round the edges of such a layer might be ignited. At all events the *Roraima* and other vessels were destroyed by fire, whilst the cloud as it passed over St. Pierre set fire to buildings. The *Dominica Guardian* of June 25 writes on this subject as follows:—

"It would appear that a sudden fissure was opened on the side of the mountain overlooking the city; and, near to the Étang Sec on this flank of the volcano, a large vent belched out lava, superheated steam and acid gases downwards on to St. Pierre and the roadstead. The flashing off into steam of the water imprisoned in the incandescent lava converted that lava into sand and dust before it reached the city, and the radiation of heat from molten rock at a temperature of more than 1000° C. caused an incredibly hot blast that would create a red hot hurricane—if I may employ such a term—that would kill people and animals instantly, and that would cause all inflammable matter to burst into flame. This from what I gather is what really happened, and I do not think that poisonous gases or electrical phenomena are accountable for the destruction of life."

The steam, hot air or gas penetrated clothing without firing the same, but it burned the skin beneath. This seems to have been true for those who were on the seaward side of St. Pierre, but it hardly appears to have been the case with those who were on the side nearest to the eruption.

Those who saw the cloud from the front, Mr. Hill tells us, say that it was not accompanied by incandescence, whilst those who were at the side or behind the same testify to seeing a flash-like flame suggestive of the ignition of a gas. It is quite conceivable that those behind the cloud might see that which was invisible to those in front, but the nuns at Morne Rouge do not appear to have seen the alleged flame.

The total quantity of ash that fell in St. Pierre was less than 1 foot in thickness, and it was piled highest against the northern walls, that is, on the side facing Mont Pelée.

In the blackening of silver and other metal objects picked up in the ruins, Mr. Hill sees evidence of the presence of vapours which were sulphurous. That silver should have been blackened within a burning house is what might be expected, but it does not follow that this blackening was due to sulphur from Mont Pelée. That there were small quantities of sulphurous vapour escaping before the great eruption is exceedingly likely, but when the latter took place it is more likely that the gas which accompanied the steam blast was hydrochloric rather than sulphurous. Since the days of Sodom and Gomorrah sulphur has been associated with volcanic action, and in the popular mind a volcano must always be accompanied by the combustion of this element.

The force of this blast may be judged by the photographs, the most striking of which is that of the monument of Our Lady of the Watch, which, although it weighed several tons, was hurled 50 feet. The blast caused vessels to turn turtle, walls were blown down and almost every standing object was levelled with the ground.

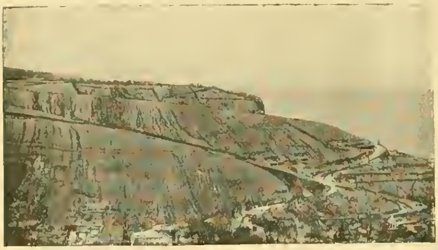
After the first blast, which pulverised buildings on the north side of St. Pierre, there was a return blast to blow over the south end of buildings, and lastly there came what appears to have been a vacuum—witnesses say that they "could get no air to breathe."

The fact that in the clouds which were thrown out in subsequent eruptions there were "tremendous displays of bolts and flashes" suggests that the flash which is said to have accompanied the primary outburst may have been a phenomenon akin to sheet lightning, which could only be seen on one side of the cloud which covered St. Pierre.

With this blast there was practically no noise of a great explosion, neither was there any evidence of marked seismic activity.

People were killed by inhaling hot ashes, some were burned by ashes or steam or flames, and by no means did all die instantly. With the exception of a few trees and plants protected in deep ravines, the country around St. Pierre was denuded of vegetation, but it is satisfactory to read that "nineteen-twentieths of the area of Martinique is as green and beautiful to-day as ever it was." Out of an area of 380 square miles only 12·5

square miles have been devastated. No lava flowed, but only streams of mud, and to this it is added that neither the land nor the sea bottom has subsided or been uplifted—a statement in which we cannot concur.



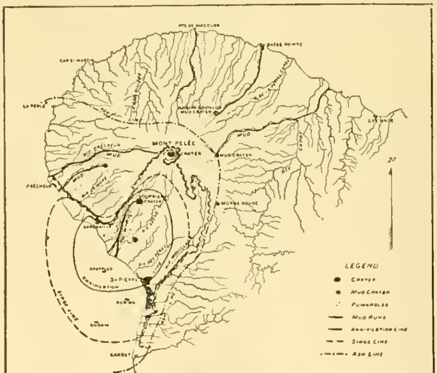
[*Photo by Israel C. Russell.*

FIG. 1.—Mud-plastered landscape, south end of Morne d'Orange.

Evidences of lightning strokes have been found in St. Pierre by Prof. Heilprin, but they are not numerous. The time at which the city was overwhelmed was at 7.50 a.m. (local time). At 7.53 and 7.55 magnetic disturbances commenced at Cheltenham, near Washington, and at Baldwin, in Kansas, and disturbances were also recorded in Paris and Hawaii.

In the *résumé* of the report Mr. Hill tells us that the fatal explosions were not from the old crater of Mont Pelée, which is 5 miles from St. Pierre, but from a lower vent about $2\frac{1}{2}$ miles distant, and it is therefore a Soufrière which has created destruction both in Martinique and in St. Vincent.

The report furnished by Prof. Israel C. Russell refers to both of these islands. It commences with a list of those who were fortunate in obtaining berths on board the *Dixie*, amongst whom was Mr. Borchgrevink, who conversed on "the desolate wilds of the Antarctic Continent," but whose report is held back for a future publication. Mr. Russell's photographs are excellent, and without these the instructiveness of his and other reports would have lost much in value. The material



2½ miles to the inch

FIG. 2.—Map prepared by Mr. Robert T. Hill showing zones of devastation in Martinique.

ejected in Martinique was much finer than that thrown out in St. Vincent, where stones 5 and 6 inches in diameter fell at a distance of about 5 miles from their origin.

Mr. J. S. Diller describes the rocks of Mont Pelée as hypersthene and hornblende hypersthene andesites. The material forming the peak of Mont Carbet is a dacite or quartz andesite. The pumice from the recent eruption is hypersthene andesite. Eight chemical analyses show differences in ejectamenta from different eruptions and in the character of the materials which fell near and at a distance from the craters from which they originated.

The lavas from St. Vincent are also hypersthene andesites, but are peculiar in the fact that they contain olivine. In the ejecta from St. Vincent sulphur, which is absent in that from Mont Pelée, is a marked constituent. In a separate report Mr. W. F. Hillebrand points out other differences between the lavas and lapilli from these two islands which are sufficiently marked that the product of Pelée can be easily distinguished from that of La Soufrière. In referring to Dr. Pollard's analyses (see

[*Photo by Israel C. Russell.*

FIG. 3.—A river of mud pouring from La Soufrière.

NATURE, vol. lxvi. p. 130) indicating the presence of nickel and cobalt, Mr. Hillebrand remarks:—"Either we of the Survey have overlooked traces of nickel . . . or Dr. Pollard has counted as nickel something which was not that element."

Although we have here and there ventured a few critical remarks upon these reports, we cannot but regard them as a valuable contribution to vulcanology, and anticipate pleasure in the perusal of their continuation.

In the August number of the *Century Magazine* we have read with interest two articles on "The Last Days of St. Pierre," each of which is founded upon documentary evidences. The first of these is a letter written in the form of a journal by the Very Rev. G. Parel, vicar-general of Martinique, to his Bishop, and the second a series of extracts contained in *Les Colonies*, a daily paper published in St. Pierre. Although, as might be anticipated, a large portion of these documents refer to the attitude taken by the inhabitants of the stricken districts, and furnish details of local rather than of general interest, much may be extracted from them of scientific value.

Now we learn that Mont Pelée showed its cap of white vapours as early as April 25, and that excursionists who were attracted by the spectacle reported that the Étang Sec, "which has the shape of an immense basin inclined towards St. Pierre," was filling up with boiling water.

Prior to the eruption of 1852 this cirque was also filled

with water, but subsequently it dried up. Although sulphurous vapours escaped from its bed, which led to its being named La Soufrière, we read that it was more or less covered with vegetation.

On May 2, in addition to vapours, Pelée erupted ashes to cover Le Prêcheur. At 11.30 that night there were terrifying detonations, and "cinders" covered the country as far as Fort de France. These detonations, but varying in intensity, were continuous. With these sounds were mixed those of thunder, which followed the flashes of lightning in the dust cloud, the general rumbling in the crater, and the roar of many torrents. Thirty streams round Mont Pelée rose at once, and yet not a drop of rain had fallen on the coast. On May 5 the Rivière Blanche became a threatening and muddy torrent. Suddenly a column of vapour was seen to rise from the valley that expands below the crater of Mont Pelée, following which a "boiling water-spout" burst in the mountain, and this, laden with rocks and earth, buried the Guérin Sugar Works and rushed seawards, to founder two yachts, one of which was 150 metres off the shore, and to sink eight lighters.

Near the site of the factory this mud is at least 6 metres in depth. It appeared to Prof. Landes, who contributed to the last issue of *Les Colonies*, that the contents of the Étang Sec had broken their barrier and avalanche-like had rolled 700 metres downwards to the sea. The origin of this disaster, like that which on May 8 destroyed St. Pierre, is therefore to be found on the flanks of Pelée rather than at its crater.

Those who on April 27 visited the Étang Sec describe the same as a bowl 300 metres in diameter at the bottom and 800 metres at the top. The surface of the lake within this bowl was covered with black cinders, whilst the trees round the crater were covered with a "metallic black coating."

On the eastern side of the basin there was a cone 10 metres high and about 15 metres in diameter at its summit. From this new crater "smoke" rose in great puffs, water spouted from the borders of the basin and poured downwards to the lake, and there was a sound of boiling. The temperature of the water in the lake was that of the body, but where it entered it was probably very much higher. It deposited a fine slate-coloured powder, and contained sulphurous gas which blackened silver. Here and there green leaves could be seen in the lake, which the guides affirmed were on the upper branches of trees probably 20 metres in height.

The vicar-general says that about 4 a.m. on May 7 he saw on the flanks of Pelée two red craters, and these were visible for half an hour. On May 8, about 4 a.m., there was a violent thunderstorm, and torrents of rain fell in Fort de France.

At about 8 o'clock there was a hail of stones and hot cinders, and the sea retreated three times a distance of several hundred metres. Whilst this fiery tornado was obliterating St. Pierre, two atmospheric currents—one from the south-east and the other from the north—showered rain upon its flanks.

On May 1 *Les Colonies* told its readers that on April 29, between 3 and 5 p.m., there had been several shocks of earthquakes, but nothing is said about volcanic eruptions.

On May 2 it advertises an excursion to Mont Pelée, but it is not until after the eruption which took place the same night that any serious reference is made to the volcano. Next day (Saturday, May 3) *Les Colonies* is filled with details relating to a cinder rain that never ceases, the closing of houses, the difficulty of obtaining vegetables, the obliteration of roads, the muddy rivers, the dead birds and dying animals, and the flight on the steamers of the Compagnie Girard.

Great fear seems to have existed lest an earthquake should occur. The issues of May 6 and 7 continue the gruesome story. In his last issue the editor inserts a note that Thursday, May 8, being the Feast of the Ascension, his offices would be closed, and the next number of *Les Colonies* would appear on Friday. But for St. Pierre Friday never came.

A second paper in the *Century Magazine* gives the narratives of two eye-witnesses of the eruption in St. Vincent. The first of these is from Captain Calder, chief of the police in that island. From his account it appears that La Soufrière showed signs of eruption on May 5. On May 6, at 8.30 p.m., Captain Calder left Kingstown by boat for Chateau Belair, and about midnight he saw the whole top of the mountain burst into "flame." This was followed by a heavy explosion.

At 2.30 a.m. (May 7) there were similar explosions, with but little "flame." About 10 a.m. there was a terrific explosion, and in the "smoke" cloud there was a little pale flame. At 1.30 p.m. this cloud had reached a height of at least two miles. Next he describes the flight of the population holding boards above their heads to prevent injury from falling stones, following which are detailed accounts of the varying phases of the volcanic activity and the destruction which it wrought.

The second personal narrative is from Mr. T. McGregor McDonald. From this it appears that at Chateau Belair the first notice of an eruption was at 2.40 p.m. on May 6. At first the Soufrière erupted columns of white vapour without explosions. At 7.30 p.m. the vapour was accompanied with flame, and explosions took place at intervals of about two hours.

On May 7, at 6 a.m., black "stuff" was erupted. About 7.45 columns of vapour rose to a height of 30,000 feet in one minute. From 11.10, when there were thunder and lightning, Mr. McDonald made entries in his notebook of what was occurring almost every five minutes. This he did until 2 p.m., when beneath a rain of stones he escaped to Walliabou, where the diary was recommenced and continued up to 9.30 p.m. on May 14.

J. MILNE.

A TEXT-BOOK OF MAMMALS.[1]

FEW branches of zoological science have made greater advances during the last ten or a dozen years than has the study of mammals. Investigations with the microscope and the section-cutter have revolutionised our ideas as to the homology and succession of the dentition of the marsupials, while our conception of the relationship of that group to the monotremes on the one hand, and to the typical placentals on the other, has been totally altered by the discovery of a vestigial placenta in the bandicoots, and also by the apparent evidence of a connection with the creodonts afforded by certain extinct types from the South American Tertiaries. Then, again, the systematic part of the subject has been enriched by the discovery of a number of totally new and unexpected living generic types, such as Notoryctes and Cænolestes among the marsupials, Zenkerella and Idiurus among the scaly-tailed African squirrels, and Ocapia among the ungulates. Our conceptions of species and local races have undergone an equally profound change in the group under consideration, and the number of such new forms—some good and some bad—which have been added to our lists during the last few years is little short of astonishing. Moreover, trinomialism has been introduced into the science, and is largely adopted by a considerable number of eminent writers; and nomenclature itself has undergone a change which, while in many respects regrettable, could scarcely have been avoided, at least to a certain degree, if zoology is to maintain any

[1] "The Cambridge Natura History." Vol. x. Mammalia. By F. E. Beddard. Pp. xii+605. Illustrated. (London: Macmillan and Co., Ltd., 1902.) Price 17s. net.

semblance of consistency. Neither have the palæontologists been idle during the period referred to, the wonderful extinct mammalian fauna of Patagonia—inclusive of the ground-sloth, whose skin was recently found in a cave at Ultima Esperanza—having been to a large extent described during the last decade, while many interesting forms of extinct mammalian life have been made known from other parts of the world. If to the above be added the change of view with regard to the limits of zoological regions and the extent to which lands now widely sundered have been connected in past epochs of the world's history, there is little cause for wonder if the majority, or all, of the standard text-books dealing with mammals are more or less completely out of date.

Accordingly, it may be taken for granted that a trustworthy and up-to-date technical text-book on the study of mammals is a desideratum at the present time, and that the author has thus an unusually favourable opportunity before him. But this is not all that may be said in his favour, apart from the contents of the work itself. Mr. Beddard, from his official position at the Zoological Society's Gardens in the Regent's Park, has special, and probably unrivalled, opportunities of making himself acquainted with the anatomy of the soft parts of mammals —a subject too often neglected, or treated in insufficient detail in works of this nature In addition to devoting a large amount of attention to the external glands of mammals, as well as to their internal anatomy in general, Mr. Beddard has made a special study of the mammalian brain, the results of which are incorporated in the volume before us. On this, if on no other, account his work must have an exceptionally high value for the students of mammals, as containing an enormous amount of information on this branch of the subject which can be obtained elsewhere only by laboriously searching through a long series of original memoirs.

A special feature of the volume is the large amount of space devoted to the consideration of extinct forms of mammalian life; and this is the more to the author's credit since, we believe, he is not himself a student of the palæontological aspect of the subject. He has, however, doubtless realised that the extinct forms afford the only key to the true relationship of their modern descendants; and he is to be congratulated that his work stands apart from all text-books on the same subject published in this country on account of the large amount of detailed information concerning extinct types. For one who is not himself a palæontologist, the author appears to have succeeded remarkably well in the treatment of this portion of the subject. He has, however, unfortunately quite failed to realise the nature of the dental succession in elephants and mastodons. Otherwise we should not have met with the statement on p. 220 that *Elephas planifrons* is the only member of its kind in which milk-molars are developed, and that in mastodons these teeth are more common; or the further and contradictory statement on p. 230 that these teeth occasionally persist throughout life. He should, of course, have known that milk-molars are always present, and that in one elephant and several mastodons they are succeeded by pre-molars.

As regards zoological regions, it is satisfactory to find that Mr. Beddard has adopted the view that the land surface of the globe is divisible, from this point of view, into three primary divisions, or realms, at least one of which is capable of being split up into regions. The division of the northern part of Arctogæa into a palæarctic and a nearctic region is, however, retained; and it is somewhat regrettable to find that the author is unable to convince himself of the necessity of a Sonoran region. Even greater matter for regret is his refusal to allow the rank of a region to Madagascar. Still, of course, the author has a perfect right to his own opinion, and cannot be condemned for following the same. In the introductory chapters a noticeable feature is the large amount of space allotted to the consideration of the structure and development of the milk-glands of mammals, in the course of which the author takes occasion to refer to the remarkable circumstance that the egg-pouch of the monotremes does not appear to be homologous with the nursing-pouch of the marsupials. Hair-glands are likewise discussed at some length, some countenance being given by the author to Dr. Weber's theory that the ancestral mammals were scaly creatures.

Teeth, as might have been expected, receive a large share of attention in the same section of the work, their cusps being named on the American system based on "trituberculism." Speaking generally, the author's treatment of the difficult subject of dentition is decidedly good; we believe, however, that on p. 48 he has written fifty-four in place of forty-four as the normal maximum number of mammalian teeth, while he has omitted to mention that the replaced tooth in marsupials, which he identifies with the last premolar, has been regarded by at least one recent writer as corresponding with the third of that series. Allusion is made to the mammalian resemblances of the dentition of the African Anomodontia (a group-name which, by the way, the author, on p. 48, credits to Huxley instead of Owen), but the question whether the one type is directly derived from the other is not discussed.

FIG. 1.—A Flying Fox (*Pteropus poliocephalus*). From Beddard's "Mammalia."

Passing from the introductory to the systematic portion of the work, we find Mr. Beddard differing from the majority of his predecessors in dividing the Mammalia into two, in place of three, primary groups—namely, the Prototheria, now represented only by the monotremes, and the Eutheria, including both marsupials and the true placentals. In view of the discovery of a vestigial placentation in marsupials, to which allusion has been already made, as well as from other considerations, we are inclined to think that the author is fully justified in the innovation, and hope to see the new departure followed by other writers. The absence of a corpus callosum in the brain of monotremes is regarded by the

author as important, in spite of the reduced size, or even absence, of that structure in marsupials.

The author's classification of the latter calls for no special comment, although attention may be directed to certain remarks on p. 128 as to the origin of the two chief groups, in which the view of the northern origin of the entire order is adopted without hesitation. As to whether diprotodonts came into existence as early as the Jurassic or the Cretaceous, Mr. Beddard maintains a cautious reserve, although we think he might have expressed a definite opinion on this point without undue risk. It is, perhaps, a pity, in the light of modern discoveries, that Owen's footless figure of the skeleton of Diprotodon is reproduced; and it rather puzzles us to reconcile the statement on p. 146, as to the close affinity of this creature to the kangaroos, with the assertion on the opposite page that its hind-foot could not be more unlike that of a kangaroo than it actually is.

But Mr. Beddard seems to take a delight in puzzling his readers by statements that to the average mind appear absolutely contradictory. For instance, on p. 160, after stating that the extinct Patagonian Prothylacinus and Amphiproviverra "are not merely polyprotodonts, but definitely dasyures," in the very next paragraph it is suggested that they are not marsupials at all.

The Edentate order is taken to include the pangolins and aard-varks as well as the typical American forms, although it is stated that the aard-varks do not show marked signs of affinity with the pangolins. A strong point in favour of the author's system is that the pangolins are stated to possess a muscle found elsewhere only in the American edentates. Fossil forms are treated at some length, but it would have been better had the author reproduced one of the figures of Glyptodon published by the La Plata Museum instead of the cut of an imperfect example from one of Owen's works. The inclusion of the North American Eocene ganodonts among the edentates is, we believe, a feature which appears for the first time in an English text-book.

The chapter on ungulates commences with a well-written description of the foot-structure of the different groups, followed by an interesting discussion on horns and antlers. Mr. Beddard was fortunately able to introduce a brief account of the okapi, although he was, of course, unacquainted with the fact that the adults are horned. This being so, it is somewhat curious to find no mention of Dr. Andrews's description of ancestral Proboscidea from Egypt, which was published about the same time as the announcement of the discovery of the okapi. We have already had occasion to allude to the author's unfortunate error in regard to the nature of the dentition of fossil elephants, and we are obliged to say that the whole chapter on ungulates, especially as regards recent forms, is far from being as satisfactory as it ought to be. In pointing out certain deficiencies and errors in this and other parts of the work, it may be well to state that it would be scarcely worth while to allude to these, were we not impressed with the high value and importance of the work as a whole, which makes it the more to be regretted that such blemishes should occur.

As regards the Equidæ and Tapiridæ, we have little or no fault to find, but when treating of the rhinoceroses, the author should have been aware that the white species has been recorded from Central Africa, while the affinity to this species of the extinct so-called *Rhinoceros tichorhinus* should have been indicated. More severe criticism is called for with regard to the chapters on the deer and hollow-horned ruminants, which are everywhere "scrappy" and in many cases absolutely misleading. To include among the typical deer such a widely different animal as Père David's deer is at the present day little short of absurd. But, unfortunately, the author appears quite unable to recognise the essential difference between the "brow-tined" and the "forked" types of antlers, otherwise we should not have, on p. 301, the absurd statement that the antlers of the extinct *Cervus* (properly *Anaglochis*) *sedgwicki* are "like those of a red deer exaggerated." It would be just as true to say that a leopard is coloured exactly like a tiger! The account of the species rightly included in the genus Cervus is, moreover, altogether inadequate, the reader not even being informed that the species incorrectly called *C. luehdorfi* is one of several Asiatic representatives of the wapiti. The treatment of the antelopes, although brief, is fairly satisfactory, but in describing the wild oxen the author states that the gaur and the gayal have a white rump-patch, whereas that feature is distinctive of the banting alone; and he aids in perpetuating the error that the British white park-cattle are the nearest relatives of the extinct wild ox of Europe.

The sheep and goats are very unsatisfactorily treated, both as regards description and illustration, some of the figures being those of immature animals, while the distribution and nomenclature are in several instances incorrect. As an example, it will suffice to mention that (on p. 324) one and the same sheep is stated, under the name of *Ovis nahura*, to be Tibetan, and, as *O. burrhel*, Indian. Again, in the description of the goats, after stating that the horns are never spirally curved, Mr. Beddard writes that the markhor (the horns of which are spirally twisted) is confined to certain parts of Afghanistan!

Little need be said with regard to the treatment of the other mammalian orders, which follows to a great extent the usual lines, and is generally satisfactory. Details connected with the characters or distribution of species are, however, in several instances not altogether correct. For instance (p. 418), it is altogether misleading to write of the South American *Canis jubatus* as the red wolf of America; while Enhydriodon (p. 440)—of which, by the way, the name is misspelt—has nothing to do with the sea-otter. Again, the statement on p. 569, that the monkeys of the genus Rhinopithecus have "also a long, but more definitely upturned nose," seems to suggest that in certain instances the author has no practical acquaintance with the animals of which he is writing. Probably the recent transference of the Tibetan Æluropus from the bears to the raccoons was not published soon enough to allow of the animal finding a place among the latter in Mr. Beddard's volume.

To turn to another consideration, even careless readers will scarcely fail to notice that while the figure of the polecat (on p. 436) is lettered *Mustela putorius*, the animal is alluded to in the text as *Putorius foetidus*. Whether this is due to carelessness, or whether it is an instance of a remarkable hesitation displayed by the author as to which name to adopt for certain genera, it is not for us to say. Such hesitation is, however, very noticeable throughout the book, the author frequently using one name, although stating that an alternative title is the proper one. It is, indeed, very difficult to decide what has been his guide in this matter. Sometimes he follows modern ruling, as in the substitution of Microtus for Arvicola, while in other cases he retains discredited names, such as Cariacus for the American deer. In regard to the wide sense in which generic terms are for the most part used, we are in full accord with Mr. Beddard.

As the result of a somewhat lengthened perusal of his work, we are glad to be able to say that the author has succeeded in producing a volume which cannot fail to be of very high value to all students of the Mammalia, especially from the standpoints of morphology and palæontology. It has failings (many of which might have been remedied by the exercise of a little more care on the part of the author and his editors), but these occupy a very subordinate position in comparison to its merits; and, with this reservation, the work may be said to maintain the high standard of excellence of the series of which it forms a part.

R. L.

HYDROGRAPHICAL OBSERVATIONS ON THE "PRINCESSE ALICE."

THE yacht *Princesse Alice*, with the Prince of Monaco on board, left Monaco on July 18 and arrived at Gibraltar on the evening of July 22, having been detained some hours by the pursuit of a school of *Orca gladiator* and the capture of one of them. The whale hunt took place within sight of the rock. Having coaled, the ship left Gibraltar on the evening of July 23, and shaped a course for the Azores. On July 24 an interesting sounding was made in lat. 36° 6′ N., long. 10° 16′ W. (Paris). The depth was 1473 metres, and the temperature of the bottom water was 9°·4 C. As this thermometer was mounted so as to be overturned by the motion of a small screw propeller, its indication was not entitled to complete confidence; but when the dredge, coming from the same depth, brought a quantity of mud which had a temperature of about 8°·75 C., it was evident that the conditions as regards temperature were very different from those which obtain in the open waters of the North Atlantic. At the above depth the temperature could not be expected to be above 4°·5 C. It is evident that this sounding struck one of the main drains out of the abysmal regions of the Mediterranean, and furnishes evidence of the *brining down*, to use a stoker's expression, of the waters of that sea, of which a more particular description can be found in the article "Mediterranean" of the "Encyclopædia Britannica."

Unfortunately, no sample of the bottom water was procured, and confirmatory evidence of its salinity is lacking, but the excess of temperature is so great that we may use it with perfect confidence in estimating the composition of the water, considered as a mixture of the deep water of the Mediterranean with that of the neighbouring regions of the North Atlantic.

If we take the original temperature of the Mediterranean water in the mixture to be 13° C. and that of the Atlantic water to be 4°·5 C., it consists of 50 per cent. of Mediterranean and 50 per cent. of Atlantic water. This is a spot where, with adequate means, with the necessary skill and experience, and, above all, with sufficient patience, a very fine piece of oceanographical work can be done.

Continuing westwards, the ship's course passed close to the Gorringe or Getysburg bank. As the former *Princesse Alice* spent July 25, 1894, on this bank, when enormous quantities of fish were taken with the line, the Prince decided to spend July 25, 1902, on the same spot. The fishing was about equally successful, but there was not the same surprise or novelty about the experience. The depth of water on the bank is very uneven and the surface of the bottom very rough. The following soundings, taken when searching for the shallowest part, are given in the order in which they were made: 192, 146, 200, 122, 83, 177 metres. In the evening the westward course was resumed, and it was shaped so as to pass over the position of the Josephine bank. This bank was discovered a short time before the *Challenger* sailed, and at the beginning of the cruise it was a question whether she should not make a station on it; but, on the one hand, it was felt that the ship had been fitted out for the investigation of deep and not of shoal waters, and on the other the bank did not lie in her route either from the Channel to Gibraltar or on that from Gibraltar to Madeira. Moreover, the interest which attaches to oceanic shoals and to their study was not, and could not be, at that time recognised.

On July 26 soundings were obtained, gradually shoaling to 1038 metres with hard bottom. This was taken to be on the eastern escarpment of the bank, and one of the Prince's latest *nasses* or traps, made of wicker-work, was sent down and buoyed, with lights. The ship was kept near during the night, and early in the morning the process of heaving up was begun. It was continued with much patience, but the cable had evidently hooked on the rocky bottom, and it finally carried away. Had it been the *nasse* which had got fixed, it would have come away quite easily, because it would have been torn to pieces. The remainder of the day was spent in sounding over the bank, in so far as time permitted, and the results are rather remarkable.

In sharp contrast with the Gorringe bank, the depths on which are so uneven, the soundings made on the Josephine bank revealed a uniformity of depth which is astonishing. The superficial area of the bank is evidently very considerable, but in the time at disposal it was impossible even roughly to delineate it. An area of about three miles square was sounded over, and the depths are here given in the order in which they were obtained: 218, 230, 220, 219, 211, 216, 218, 215, 212, 215, 189, 190, 204, 208 metres. The descriptive value of these figures cannot be excelled. A successful, but in no way very remarkable, dredging was made in this water. In the evening the route was continued in the direction of Ponta Delgada, in the island of St. Michael. Soundings were obtained in 4275 and in 2589 metres, and the writer was enabled to attach to the sounding lines piezometers of two different and rather novel patterns, and thus to resume the experiments on compressibility at great pressures which he began on the *Challenger*. The instruments acted quite satisfactorily, and it is hoped that useful results will be obtained with them. On the morning of July 31, when only a few miles off the coast of St. Michael, the dredge was put over in 1189 metres, and a very rich haul was obtained.

Although no very definite or detailed programme exists, it is the Prince's intention to work among the islands for a week or two, then to make an excursion southwards to the very deep water which lies between this archipelago and the Canary Islands, and thence to work homewards so as to arrive at an European port by the middle of September. Up to the present date the weather has been everything that could be desired, and the bright, bracing climate of these islands is invigorating and refreshing. J. Y. BUCHANAN.

Yacht *Princesse Alice*, August 1.

NOTES.

THE impressive rite of the coronation of King Edward was performed on Saturday last in circumstances of unequalled splendour. All who witnessed the spectacle must have been moved by feelings of loyalty and love for their Sovereign and country, and of pride in the history of the British race. Few men of science appear to have been invited to the function, though the nation owes so much to them. Scientific knowledge combined with medical skill has brought the King safely through a period of great danger and suffering, and given us all cause for thankfulness at our monarch's return to health. The modern science of electricity contributed as much as the mediæval pageantry to make the day memorable. But the ceremony belongs more to the past than to the future; it is the symbol of unity between the King and his people, and it shows the basis of liberty of thought and action which is our national heritage, and without which progress is impossible. The past has truly been glorious, but the future needs the development of new attributes of national character if we are to maintain our position among the peoples of the world. We trust that the reign of King Edward VII. will not only be long and happy, but that it will be characterised by the cultivation of the scientific spirit which will promote its prosperity.

A SPECIAL number of the *Atti* is devoted to the anniversary meeting of the Reale Accademia dei Lincei, held at Rome on June 1 under the patronage of the King and Queen of Italy.

Prof. Pasquale Villari has been recently elected president of the Academy. The report of the vice-president, Signor Blaserna, shows that in the past year the Academy has issued three volumes of *Proceedings*, containing 192 pages and notes, a volume containing memoirs relating to moral sciences, and notices of excavations, brought out under the auspices of the Minister of Public Instruction, and four parts, with 160 plates, of the "Codex Atlanticus" of Leonardo da Vinci. The Academy has taken part in the meetings of the International Association of Academies, and in work connected with the Royal Society's "International Catalogue of Scientific Literature." The observatory on Monte Rosa has been considerably enlarged, a fund for this purpose having been founded by Queen Margherita, whose name the edifice bears; it is now available for researches in meteorology, physics and physiology. A fresh field of study has been opened up in the island of Crete, and an expedition, presided over by Prof. Halbherr, has taken a prominent part in the excavations proceeding in that island.

OF the three royal prizes offered by the Reale Accademia dei Lincei for the year, that for physics has been awarded to Prof. Cantone, of Pavia, for his researches in the phenomena of elastic equilibrium outside the limits of Hooke's Law. Prof. Cantone has obtained phenomena in elasticity closely resembling the phenomena of magnetic hysteresis, which are appropriately described as "elastic hysteresis," and the laws of which account for a large number of observed facts. The prize for archæology has been conferred on Prof. Gherardo Ghirardine, of Padua, whose work, while covering an extensive range, has been of especial interest in connection with the antiquities of the Veneti. The prize for history is unawarded. Under the Santoro foundation, an extraordinary prize has been awarded to Mr. Marconi, who, Signor Blaserna remarks, "is generally recognised as the first who had the fertile idea of making use of Hertzian waves, not for sending signals to a distance of a few metres, as had already been done by Righi, Lodge and other investigators, who deserve the credit for having first started in this direction, but for making them the basis of a system of telegraphy properly so-called." Of the two prizes offered by the Minister of Public Instruction, that for history has been divided, awards of 700 lire being made to Profs. Cogo (Genoa), Segre (Massa) and Sorbelli (Bologna), and premiums of 400 lire to Profs. Luiso (Lucca), Santini (Florence) and Strazulla (Messina). The Ministerial prize for mathematics has been divided into two prizes of 1300 lire, awarded to Profs. Giuseppe Bagnera (Messina) and Domenico de Francesco (Naples), and a premium of 700 lire has been assigned to Prof. Michele de Franchis (Melfi). The division of these prizes affords ample evidence of the activity of members of the Italian teaching profession in the matter of research. The proceedings of the meeting concluded with an address by Prof. G. Gloria on "The Position of the World in Modern Astronomy."

THE Advisory Committee appointed by the King in connection with the erection of a sanatorium for tuberculosis in England announces that 180 essays were sent in in competition for the three prizes. The Advisory Committee consists of Sir William Broadbent, Sir R. Douglas Powell, Sir Felix Semon, Sir Hermann Weber and Dr. Theodore Williams. The prizes have been awarded as follows:—First prize, value 500*l*., Dr. Arthur Latham, with whom is associated as architect Mr. W. West (London). Second prize, value 200*l*., Dr. F. J. Wethered, with whom are associated as architects Messrs. Law and Allen (London). Third prize, value 100*l*., Dr. E. C. Morland, with whom is associated as architect Mr. G. Morland.

GILBERT WHITE's house at Selborne is again for sale, and the suggestion is made by Mr. E. A. Martin, member of the council of the Selborne Society, that it should be purchased as a permanent memorial of the father of British naturalists. The house, known as The Wakes, is situated in the main street of the village of Selborne, and is in much the same condition as it was in White's time.

THE British Pharmaceutical Conference is being held at Dundee as we go to press. The members were formally received by the Lord Provost of Dundee on Monday, and on Tuesday the opening meeting was held at the University College, when an address was delivered by the president.

REUTER'S AGENCY is informed that the Prince of Monaco has presented a quantity of deep-sea apparatus to Mr. W. S. Bruce for the Scottish Antarctic Expedition, including trawls, nets, water-bottles for obtaining samples of water from great depths for physical examination, thermometers and other similar apparatus.

THE annual meeting of the French Association for the Advancement of Science was held last week at Montauban, in the South of France, when an address on the development of wireless telegraphy was delivered by M. Carpentier, president of the Association. Electric traction was the chief subject of discussion at one of the general meetings. Since the last meeting the Association has received a legacy of two thousand francs from M. E. Lamy, and one of thirty thousand francs from M. Guilleminet.

THE following papers will be brought before the Section of Physiology at the Belfast meeting of the British Association:—"The Estimation of Small Quantities of Urea," Mr. Barcroft; "Nerve-Regeneration," Prof. W. D. Halliburton, F.R.S., and Dr. F. W. Mott, F.R.S.; "The Morphology of the Camel's Brain," Dr. W. Page May; "The Hydrolysis of Glycogen," Dr. W. A. Osborne and Mr. S. Zobel; "Some New Features in the Intimate Structure of the Human Cerebral Cortex," Dr. John Turner; (1) "The Paths of Conduction for Volitional Impulses, (2) "The Functions of the Pituitary Body," Prof. E. A. Schäfer, F.R.S.

THE committee entrusted by the Society of Arts to award the Shaw prize for industrial hygiene has awarded a gold medal, or a prize of 20*l*. to Mr. James Tonge, jun., of Westhoughton, Lancashire, for his hydraulic mining cartridge—an appliance for breaking down coal in mines without the use of explosives. The prize, under the conditions laid down by the testator (Mr. Benjamin Shaw), is given "For any discovery, invention, or newly-devised method for obviating or materially diminishing any risk to life, limb or health, incidental to any industrial occupation, and not previously capable of being so obviated or diminished by any known and practically available means."

ON August 5 a statue erected to the memory of Pasteur was unveiled at Dôle, the birthplace of the great chemist. The following account of the ceremony is given by the French correspondent of the *Chemist and Druggist*:—Nineteen years ago, on July 14, 1883, the Doloise municipality commemorated the fact by placing a marble slab on the modest house where he was born on December 27, 1822, in the Rue des Tanneurs, now called Rue Pasteur. For the inauguration of the statue the townspeople had made extensive preparations, and all the local notabilities, including the members of Parliament, were present. The Government was represented by M. Trouillot, Minister of Commerce, who made the distribution of medals and decorations that is customary here on such occasions. He afterwards proceeded to the ceremony of unveiling the monument, and made an interesting speech, in which he traced the life of Pasteur. The Minister referred to it as an incessant struggle against death and suffering, which ended in victory for the *savant*. He also spoke of the advantages suffering humanity

al over the world had derived from Pasteur's discoveries. Never has the saying "genius is patience" been so truly proved as in the case of his life. In concluding, M. Trouillot said: "Pasteur's native place shows itself worthy of his memory and faithful to his teachings when it affirms its faith in the definite triumph of the ideas of peace, unity and justice." The Dôle statue of Pasteur is by the well-known sculptor M. Carlès, and was shown at the Paris Salon of the Artistes Français this spring. Mme. Pasteur and various members of her family attended the ceremony, and in the evening they were present at a banquet given in honour of the event.

A REUTER telegram from New York reports that a severe earthquake shock was felt at Skagway on Sunday last, August 10.

LLOYD'S agent at Havre states that the steamer *Homer*, on arrival at that port, reported that on July 20, in latitude 0° 30′ north, longitude 29° 36′ west, she spoke the German four-master *Christine*. Whilst speaking this vessel she felt a severe earthquake shock. The compasses all oscillated violently. This lasted about 40 seconds. The German vessel also signalled the same experience.

ON October 30, 1901, a strong earthquake felt in the neighbourhood of Lake Garda and especially at Salò gave an interesting record on the photographic tromometer at the Collegio della Querce in Florence. From the two component traces Father Melzi has drawn a diagram representing the resultant movement of the ground during the first forty seconds. For twenty-one seconds the oscillations took place chiefly along a line directed E. 37° 34′ N. and W. 37° 34′ S. At the end of this time the direction suddenly changed, through very nearly a right angle, to N. 54° 22′ W. and S. 54° 22′ E. The cause of the change is unknown, but, from the long interval that elapsed, it was clearly unconnected with the arrival of transverse vibrations.

DR. HANS REUSCH, director of the Geological Survey of Norway, has sent us a letter received by him from Dr. W. J. Branch, of Basse-Terre, St. Kitts, one of the Leeward Islands, containing an account of the effects observed there during the recent volcanic eruptions in Martinique and St. Vincent. The volcano Mount Misery, the highest point of the island, exhibited a few indications of sympathy with Mont Pelée and the Soufrière, but no remarkable effects were noticed at the time of the eruptions of these volcanoes. A fortnight after the destruction of St. Pierre, however, a loud explosion was heard by labourers working on the side of Mount Misery; flames seemed to leap out of the ground, and a strong wind swept by, overturning two small houses. At the same time a heavy thunderstorm occurred, with vivid lightning flashes. Though the actions of Mont Pelée and the Soufrière are apparently in sympathy, Dr. Branch's idea is "that Mount Misery is more in league with the volcanoes of Guadeloupe, Montserrat, Dominica and St. Lucia. Their history in the past as well as in the present time seems to me to favour this idea."

IT has long been known that unhygienic conditions favour the occurrence of the disease known as beri-beri, and it has been surmised that it is dependent upon defective food. Major Rost, I.M.S., claims to have discovered a bacillus in fermenting rice and rice-liquor which he believes to be the specific organism of this disease. It produces in fowls many of the symptoms resembling beri-beri in man. Moreover, fowls feeding upon fermenting rice develop similar symptoms. The disease is therefore ascribed to the use of fermenting rice and especially rice-liquor, to which beverage the coolies, who are the main sufferers, are much addicted. Children never, and women rarely, drink the rice-water liquor, and hence the infrequency of the disease in these subjects. Interesting as Major Rost's observations are, they do not throw much light on the remarkable outbreak of disease, believed to be beri-beri, at the Richmond Asylum, Dublin, some years ago, the cause of which has never been explained. (See *Ind. Med. Gazette*, July 1901 and 1902).

AIDS to practical navigation, however small they may be, should always be welcome. In the "single-handed dividers" patented by Mr. F. Howard Collins and sold by Mr. J. D. Potter, an improvement has been made on the dividers ordinarily in use for measuring distances on a chart. These new dividers are provided with two finger-holes, into which the thumb and forefinger can be inserted in a manner similar to that of using an ordinary pair of scissors, thus enabling the navigator to open and close them readily with one hand and giving a greater command over the instrument. The joint, which is made a round ball, is also of a very good form for handling. This instrument is strongly made in German silver and is suitable for the ordinary service of a sea-going vessel.

PROF. G. HELLMANN has published the fourteenth volume of his remarkable reproductions of notable old papers and charts relating to meteorology and terrestrial magnetism. The present work deals with meteorological optics during the years 1000 to 1836, and is, as usual, accompanied by valuable bibliographical notes, the result of laborious researches which we think we may safely say have never been excelled and are possibly unequalled. Meteorological optics may be said to be a somewhat neglected branch of the science, and this renders the investigation the more welcome. The work contains four important papers on the rainbow and allied phenomena, including the classical treatise of the late Sir G. B. Airy "On the Intensity of Light in the Neighbourhood of a Caustic," three papers on halo phenomena, with others on mirage, twilight, &c. For readers wishing to study the early history of the subject, the author gives references to the works of Kämtz, Clausius and the recent important contributions of Dr. Pernter. As one instance of Prof. Hellmann's persistent researches, we may refer to the first of the papers now described, "De Radialibus impressionibus" (1311), by Theodorich, a remarkable work on atmospheric phenomena, which was supposed to have been buried for 500 years and lost to science until it was published by Venturi, at Basle, in 1814; but Dr. Hellmann discovered that Theodorich's theory was taught at the Erfurt University up to the beginning of the sixteenth century. At the present time only two copies of the original manuscript are known to exist, one at Basle and the other at Leipzig (the latter being not quite perfect).

THE Imperial Department of Agriculture for the West Indies has just issued the following reports:—On the Botanic Station, Dominica, for the twenty months to the close of November, 1900; and on the Agricultural School, for the year 1901. On the Experiment Stations at Montserrat, for the fourteen months to the close of March, 1901; and on the Botanic Station, Agricultural School and Land Settlement Scheme, St. Vincent, for the year 1901. The reports are generally of a favourable character, and show that much useful work was accomplished in the distribution of plants and seeds, in experimenting with new plants, &c., which may be introduced for profitable cultivation, and so on. Details are given of the courses of practical instruction in the agricultural schools. The 1900 season in Dominica was a dry one, the rainfall of 57·75 inches being 23·95 inches less than the average. In St. Vincent, 1901 was fairly wet, the rainfall of 125·69 inches being 12·43 inches above the average. It would considerably enhance the value of these West Indian reports if the Imperial Commissioner could arrange for each series issued to cover the same period throughout

the islands, instead of, as indicated above, each island adopting its own and often very irregular period.

THE question of the existence of a portrait of Gilbert White is discussed by Mr. R. Holt-White in a letter to the August number of *Nature Notes*, with the result that there is no good reason to believe that any such picture is known.

WE have received from Prof. H. F. Osborn a budget of papers on vertebrate palæontology and kindred subjects, two of which, "The Law of Adaptive Radiation" and "Homoplasy as a Law of Latent Homology," were mentioned in this Journal as they appeared in the *American Naturalist*. Special interest attaches to a communication on the Eocene Primates and rodents of North America (*Bull. Amer. Mus.*, vol. xvi. art. 17), in which it is stated that presumed representatives of the former group from the basal Puerco Eocene bear no sort of ancestral relationship to the undoubted Primates of the overlying Wasatch beds. Whether the latter forms are anthropoids or lemuroids, or whether they include members of both groups, or, finally, whether they constitute a primitive group by themselves, is left undecided. Three American families are recognised, the first of which (Hyopsodontidæ) is believed to be nearly related to the Hampshire Microchœrus. Of even greater importance, if well founded, is the author's recognition of a group of primitive rodents in the Bridger and Wasatch Eocene, for which the name "Proglires" is suggested. These forms had canines and rooted incisors, and their lower jaws lacked the backward-and-forward motion characteristic of their supposed descendants. They are typified by Cope's genus Mixodectes.

IN the autumn of 1900 a gardener of Hundsheim, in German Altenburg, Lower Austria, brought to the high school at Vienna part of the lower jaw and an upper cheek-tooth of a rhinoceros which he said had been found in the vineyard where he worked, in association with other remains, not improbably including the entire skeleton. Recognising from the structure of the teeth that the remains did not belong to the ordinary woolly rhinoceros, Prof. F. Toula, to whom they were submitted, proceeded to Hundsheim, and was fortunate enough to disinter the almost complete skeleton of the animal, which has now been mounted. Unfortunately, the terminal third of the skull is missing, but sufficient remains to show that the animal was a two-horned species belonging to the same group as the living Sumatran rhinoceros. In a preliminary notice Prof. Toula proposed the name *Rhinoceros* (*Ceratorhinus*) *sumatrensis* for the new species, and in a recent issue (vol. xix. pt. 1) of the *Abhandlungen* of the Austrian Geological Survey he describes the skeleton in detail, figuring the various bones in no less than twelve plates. The breccia at Hundsheim in which the skeleton was found is of Pleistocene age, and is notable for containing the remains of a goat allied to the tahr (Hemitragus). Rhinoceroses of the *R. sumatrensis* group were previously unknown from the European Pleistocene.

A BRIEF report on the disintegration of building stones in Egypt, by Mr. A. Lucas, has been issued by the Survey Department, Public Works Ministry, Cairo (1902). The decay of the building stones, which consist of limestone and sometimes of calcareous sandstone, appears mainly at or near the surface of the ground, and is often accompanied by an incrustation or efflorescence of sodium chloride. The cause of the disintegration is the entry into the stone of moisture and soluble salts, chiefly from the soil, which is always in a more or less saturated state.

THE coal, lignite and asphalt rocks of Texas are dealt with in a *Bulletin* published by the University of Texas (1902), the Mineral Survey being under the direction of Mr. W. B. Phillips. The Eocene lignites, the Cretaceous and Carboniferous coals are described, mainly from an economic point of view. The lignite industry has felt the competition of fuel oil more keenly than that of the bituminous coal, but as there is a marked tendency to increase the price of oil, there is hope for the lignite miners. The asphalt rocks comprise sandstones, alternating sands and clays, and limestones impregnated with bitumen, and they occur in the Cretaceous formation sometimes where it impinges upon the Carboniferous, and also in the Tertiary strata.

WITH a view to stimulate planters in New South Wales to undertake the cultivation of the cork oak, the director of the Sydney Botanic Gardens has issued a pamphlet in which are embodied notes on the economic value, suitable soil and position for growing, and other details of management of this tree.

IN the recently published "die Organographie der Pflanzen," want of space prevented Prof. Goebel from treating at any length the question of "regeneration in plants." A series of articles on this subject is now appearing in the *Biologisches Centralblatt*. The discussion is limited to regeneration in so far as it relates to the development of new parts or latent rudiments, and illustrations are taken from the ferns *Aneimia rotundifolia*, *Asplenium obtusifolium*, from the genus Bryophyllum of the Crassulaceæ, and from *Nymphaea stellata*, var. *bulbillifera*. In the case of the ferns, it will be noticed that the tendency is to push the formation of buds towards the apex, while in Bryophyllum the cutting off of supplies from the apex stimulates the growth of lateral buds. *Cyclamen persicum* affords an instance of the formation of new members induced by the stimulus caused by mutilation. If in the young seedling the stem apex is cut off just at the junction with the single cotyledon, one or more leaves are developed in various positions, perhaps more generally from the base of the petiole.

A POPULAR paper on thunderstorms and lightning discharges, by Mr. A. H. Bell, and one on minute marvels of nature, by Mr. J. G. Ward, illustrated by photo-micrographs, appear in the August number of *Good Words*. The latter article contains several good reproductions of photographs showing internal structures of leaves.

THE Royal Agricultural Society of England has issued a sixpenny pamphlet, written by the Society's zoologist, Mr. Cecil Warburton, with the title "Orchard and Bush-Fruit Pests and how to combat Them." After giving the ingredients and the methods of preparation of a few of the most useful and readily mixed insecticides, the pamphlet describes a number of commonly occurring insects affecting the leaves, blossoms, fruits or wood of orchard trees, with the best methods of preventing their attacks, of checking their depredations, or of destroying them altogether, where possible. The same kind of information is given with regard to various insects infesting currants, gooseberries and raspberries. The pamphlet is illustrated with twelve original wood cuts and is published for the Society by Mr. Murray.

A LECTURE on "The Relation of Science to Art: in reference to Taste and Beauty," delivered before the Hampstead Scientific Society by Sir Samuel Wilks, Bart., F.R.S., on May 12, has been published by the Society. The scientific attitude of mind is so often considered to be opposed to artistic feeling that this analysis of the relationships between the two temperaments is of wide interest. The artist admires the form, and the man of science seeks to discover the cause which produces it. The twofold characters of an object are closely associated and dependent on one another, but few individuals are able to appreciate them both fully. A large part of Sir Samuel Wilks's address is devoted to the consideration as to "whether beauty depends in any way upon fitness or utility, or whether the feeling is not an inherent faculty of the mind"; and the general conclusion arrived at is

in favour of the former view. As regards people who are able to contemplate with admiration the world around them, the belief is expressed that "much of their appreciation of beauty or aversion to the ugly is obtained from the necessary physical laws governing all objects, although they themselves may be unconscious of the fact."

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. H. G. B. Whitehead; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) rom West Africa, presented by Mr. J. Hoatson; two Chinchillas (*Chinchilla lanigera*) from Chili, presented by Captain B. Dixon, R.A.; two Kinkajous (*Cercoleptes caudivolvulus*), two Cocoi Herons (*Ardea cocoi*), four American Jabirus (*Mycteria americana*), an Anaconda (*Eunectes murinus*) from Brazil, presented by Dr. E. A. Goeldi; a Common Squirrel (*Sciurus vulgaris*) British, presented by Miss Rice; two Graceful Ground Doves (*Geopelia cuneata*) from Australia, presented by Mrs. C. A. Thompson; a White Stork (*Ciconia alba*) European, presented by Mrs. A. Gregory; a Bennett's Tree Kangaroo (*Dendrolagus bennettianus*) from Queensland, presented by Mr. Winkley Smith; a Cocoi Heron (*Ardea cocoi*) from Brazil, presented by Mr. W. A. Churchill, H.B.M. Consul, Pará; two Coquerel's Mouse Lemurs (*Chirogaleus coquereli*) from Madagascar, two Red-masked Conures (*Conurus rubrolarvatus*) from Ecuador, a Blue-winged Siva (*Siva cyanouroptera*) from India, deposited; two Graceful Ground Doves (*Geopelia cuneata*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

ROTATION PERIODS OF THE SUPERIOR PLANETS.—In the *Comptes rendus* of the Paris Academy of Sciences for July 28, M. Deslandres gives the results of his experiments in determining the rotation of superior planets by means of the spectroscopic method based on the Fizeau-Doppler principle.

The method, which was described in detail in *Comptes rendus*, vol. cxx. p. 417, depends upon the differential displacement of the opposite ends of the equatorial diameter, which causes this diameter to appear inclined to its normal direction, and thereby gives, instead of a circular image of the planet in the spectrum, an inclined ellipse, the axis of which is inclined more or less depending upon the speed of the planet's rotation; the relative direction of the major axis of the ellipse depends upon the direction of the planet's rotation.

M. Deslandres uses a spectroscope of moderate dispersion and a wide slit, and emphasises the fact that the entire light of the planet may thus be used, and still very useful, though less accurate, results may be obtained. He points out that one advantage of this method is that the apparent displacement is double the real displacement due to the rotary motion, for, of course, both ends of the diameter are equally displaced, therefore a high degree of accuracy may be obtained. Experimenting on the rotation of Jupiter, two forms of instrument were used, first a small spectroscope with a wide slit and then a 30° prism mounted in front of the object-glass of a telescope of 0m.·55 aperture. In each case three exposures were made, the first with the slit, or the edge of the prism, parallel to the equator of Jupiter, and the second and third after having turned the complete apparatus through 90° and 180° respectively; thus the displacement of the equatorial extremities was made evident on both sides of their normal position, thereby giving greater accuracy to the measurements, and in the case of Jupiter indicating for the linear equatorial velocity of 12 km. an equatorial velocity, according to the displacement, of 48 km. The results obtained show very good accordance, and M. Deslandres claims a greater degree of accuracy for this method than is obtainable by the ordinary method. During this year the method has been applied to the determination of the rotation of Uranus, and it has already been shown that the planet rotates in a retrograde direction, but the detailed results will be given in a later communication.

THE DUTCH ECLIPSE EXPEDITION OF 1901.—In a preliminary report published by the Eclipse Committee of the Royal Academy of Sciences, Amsterdam, Profs. Julius, Wilterdink and Nijland give an account of the proceedings of the expedition which was sent out to Sumatra, by the Dutch Academy, to observe the total solar eclipse of May, 1901.

Elaborate preparations were made. Government help in the matters of transport and manual labour was obtained, and a number of officers and men belonging to the Dutch ironclad *Sumatra* was told off to assist in making the observations.

The programme of the expedition was divided into four parts: (1) the coronagraphs, (2) the spectrographs, (3) the physical observations, and (4) the collection of amateur observations, and the results of the observations made in each section are treated separately in the report.

The coronagraph negatives were mostly spoiled by cloud-fog, only those obtained by short exposures and on slow plates giving good results. Using the 40-feet coronagraph, kindly lent by the U.S. Naval Observatory, and a "Lumière jaune" plate measuring 24 × 30 inches, some very fine prominences and details of the inner corona were obtained on the negative.

Of the five spectrographs used, only one gave results which are of any use, and in the negatives obtained Prof. Julius makes a special point of the doubling of all the chromospheric crescents, which he assigns to the phenomenon of anomalous dispersion of the chromospheric light, afterwards pointing out the improbability of the doubling being of instrumental origin.

In the physical observations the clouds interfered seriously, so that little weight may be attached to the heat-radiation observations, but in the observations of the polarisation of the coronal light it is shown that the light at some distance from the sun's limb is more strongly polarised than that which is near to that limb, whilst the polarisation decreases again as the distance from the limb is increased.

The results of the amateur observations are various; 39 drawings and 69 photographs of the corona have been secured, and 37 of the latter are described as "good," "very good," or "excellent." Reports on the observations of the shadow-bands were received from seventeen stations.

THE SATELLITES OF SATURN AND URANUS.—Dr. J. J. See gives the results of his observations of the satellites of Saturn and Uranus, made with the 26 inch refractor of the U.S. Naval Observatory, Washington, in No. 3806 of the *Astronomische Nachrichten*.

The "Clark Micrometer II.," with magnifying powers of 388 for the satellites of Saturn and 606 for those of Uranus, was used, and the observations are based on the method of relative measures adopted by Prof. H. Struve at Pulkowa. The micrometer is so constructed that in measuring the position of Japetus it can be directly referred to Titan by means of a sliding eyepiece, thus probably giving more correct results than by the usual method.

Dr. See points out that the statement in his paper on the satellites of Uranus, *A.N.* 3676, that the places given in the American ephemeris are 37° in advance of the observed places, is an error due to the ambiguous wording of the ephemeris.

AUSTRALIAN CHILDREN'S GAMES.[1]

A certain amount of attention has been paid of late years to the subject of the games of primitive peoples, but so far we are only in the preliminary stage of the inquiry; indeed, a vast deal more evidence must be collected before sound generalisations can be made. A few suggestions have been thrown out by various students which must be regarded more as trial hypotheses than as definite conclusions, indeed they should be looked upon rather as "kites."

So few travellers think it worth their while to mention games and toys, especially those played by children, that the record for any country is imperfect, and for most peoples there is no information to hand. When there is any information it is nearly always simply a bare enumeration of the games played or of the toys employed; very rarely is a description given of the method of playing.

We are slowly learning the lesson that many of those activities which appear to be merely trivial have, or have had, an important significance in the evolution of human culture. The physiological, psychological and sociological aspects of playing have been dealt with by Karl Groos in his book "The Play of

[1] *North Queensland Ethnography: Bulletin* No. 4, March, 1902, "Games, Sports and Amusements." By Walter E. Roth, Home Secretary's Department, Brisbane, C A. 8—1902.

Man," but it is not yet possible to map the distribution of most of the toys and games, to trace their origin, or to indicate the meaning that in many cases was primitively attached to their exercise.

Thanks to the investigations of Messrs. A. MacFarland Davis, F. Cushing, Stewart Culin, G. A. Dorsey and others, we have some indication concerning the variations, distribution and significance of the principal games of the North American Indians. Some hundred or so of these games are known, which can, however, be reduced to six main groups. These are derived from the employment of the shield and spear, marked arrows, shields on which were painted the four world quarters, and balls. Some of these games may have been originally merely games of skill, others were divinatory, while others, again, were doubtless magical.

In that vague region known as the Far East, the fragmentary evidence points to similar conclusions as the researches, amongst others, of Messrs. Stewart Culin, G. von Schlegel, R. Andree and E. B. Tylor. The same, too, appears to hold good for Oceania.

These general remarks will show how important it is that further evidence should be collected, and will indicate the welcome that will be given to the last of Dr. Walter E. Roth's studies in the ethnography of North Queensland. The following is Dr. Roth's classification of games, sports and amusements:—(1) Imaginative games, such as tales, of which nine are given. (2) Realistic games, playing with pets, playing with plants, making smoke spirals, bathing, &c. (3) Imitative games, objects and phenomena of nature imitated by attitudes, movements and paintings; the author figures seventy-four

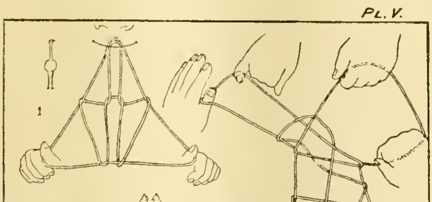


FIG. 1.

examples of those ingenious string figures in which so many primitive peoples excel. Very few illustrations of "cat's cradles" have ever been published, so that we cannot at present say how far particular devices are common to different peoples. One at all events (Plate v., Fig. 6), which represents a duck flying (Fig. 1), is similar to a string figure in Torres Straits which is called "throwing the fish spear," but this is a very simple figure to make. In this category are placed all those games in which children imitate their elders. Several round games are described in which "collecting honey,"

FIG. 2.

"catching cockatoos" and similar operations are represented; one of them, "playing bean tree" (Fig. 2), resembles a game I have described as played by Papuan children ("Head-Hunters, Black, White and Brown," 1901, chap. xv.). There are other analogies between the games of the aborigines of North Queensland and those of the Papuans. (4) Discriminative games, hide and seek and a guessing game. (5) Disputative games, wrestling, tug-of-war. (6) Propulsive games, ball games, tops, stick-throwing games, &c.; amongst the latter are certain methods of casting petioles of grass blades similar in principle to what is done by certain Papuan children. Of special interest is the hurling of a toy spear by means of a knotted string; a similar device was used by the men of the Southern New Hebrides, New Caledonia and the Loyalty Islands, and the present writer has recorded it as a child's plaything at Delena, Hall Sound, British New Guinea, and now it has turned up amongst the coastal blacks of North Queensland. (7) Exultative games, songs, dances, music. This little memoir, which is illustrated by thirty-nine plates, is full of valuable information, as it opens up a new field to the student.

A. C. H.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SIR GEORGE G. STOKES, Bart., F.R.S., senior fellow and president of Pembroke College, Cambridge, has been elected master of the College, in succession to the late Dr. Searle.

DR. W. PALMER WYNNE, F.R.S., assistant professor of chemistry in the Royal College of Science, South Kensington, has been appointed to the chair of chemistry in the School of Pharmacy of the Pharmaceutical Society of Great Britain in succession to Dr. J. Norman Collie, F.R.S., who was recently appointed to the chair of organic chemistry in University College, London.

THE council of University College, Liverpool, has unanimously agreed to invite Dr. Benjamin Moore to accept the chair of biochemistry recently founded in University College by Mr. William Johnston. Dr. Moore is now lecturer on physiology in the Charing Cross Medical School, and has made himself widely known among men of science as a successful teacher and an original investigator.

MR. J. QUICK has been appointed principal of the Technical Institute, Limerick.

AFTER a discussion extending over several sittings, the seventh clause of the Education Bill has passed Committee of the House of Commons in an amended form. The clause refers to the management of elementary schools, and it raised the

question as to the proportion of popularly elected managers which should act as bodies controlling the work of voluntary and denominational schools. The clause as amended provides that the management board of every public elementary school not provided by the local educational authority shall consist of four foundation or trust managers and two managers appointed by elected bodies. This principle has been accepted as part of the Bill. The discussion of the whole question of the machinery by which the managers of voluntary schools are to be elected has been postponed until the autumn session.

THE Ministerial changes consequent upon the resignation of Lord Salisbury, and the appointment of Mr. Balfour as Premier, involve a reconstitution of the representatives of the Board of Education in Parliament. Sir John Gorst, who has been Vice-President of the Committee of Council for Education since 1895, has resigned, and his office becomes extinct. The Duke of Devonshire remains Lord President of the Council, but ceases to preside over the Education Department. The newly constituted Board of Education has for its President the Marquis of Londonderry, who was chairman of the London School Board some years ago, and as Parliamentary Secretary Sir William Anson, member for the University of Oxford and a leading authority upon educational matters. The Duke of Devonshire will therefore no longer be directly concerned with departmental work in education, though he will have charge of the Education Bill when it reaches the House of Lords.

THERE is a feminine and a masculine type of mind. The former depends chiefly on memory and being reproductive; the other relies upon reasoning and being creative. The mind of the man of science is masculine, that of the clergyman is feminine. Not every woman possesses a feminine mind, though many men have little else. The whole of our education from top to bottom is essentially feminine, chiefly because in its origin and continuance it is clerical. Such are but a few of the opinions expressed by Mr. James Swinburne in an article on "Feminine Mind Worship" in the current number of the *Westminster Review*. The whole article is a powerful appeal for a fuller recognition of the value in education of a rational training in the methods of science, so that boys may obtain at school such a practical acquaintance with experimental physics and chemistry as will lead them to develop their reasoning faculties and endow them with those powers of initiative which are essential, since the whole welfare and existence of a commercial country like ours depends on the application of science and the work of the despised masculine mind. Mr. Swinburne's essay deserves to be widely read.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society (2) viii. No. 9, June.—T. J. I'A. Bromwich, on the infinitesimal generators of parameter groups. The author gives a simplified method of calculating the generators of a group of known structure, and compares his results with those of Slocum (*Bulletin* for January).—E. V. Huntington, a second definition of a group. The definition is reduced to four independent postulates, to which a fifth must be added if a distinction is to be made between finite and infinite groups.—G. A. Miller, determination of all the groups of order p^m, p being any prime, which contain the Abelian group of order p^{m-1} and of type (1, 1, ...).—L. E. Dickson, a class of simply transitive linear groups.—D. N. Lehmer, errors in Legendre's tables of linear divisors.—Reviews of Gray's "Treatise on Physics," vol. i., Cellérier's "Cours de Mécanique" (E. B. Wilson), and Kiepert's "Grundriss der Differential- und Integral-Rechnung" (E. W. Davis).

Annals of Mathematics (2) iii. No. 4, July.—H. S. White, note on a twisted curve connected with an involution of pairs of points in a plane.—R. E. Smith, on Sophus Lie's representation of imaginaries in plane geometry. This is an interesting commentary on Lie's first paper, published in the *Transactions* of the Academy of Christiania in 1869.—G. A. Miller, note on the group of isomorphisms of a group of order p^m.—L. D. Ames, evaluation of slowly convergent series.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 19.—"On the Measurement of Temperature." Part i.—On the Pressure Coefficients of Hydrogen and Helium at Constant Volume and at different Initial Pressures. Part ii.—On the Vapour Pressures of Liquid Oxygen at Temperatures below its Boiling Point on the Constant Volume Hydrogen and Helium Scales. Part iii.—On the Vapour Pressures of Liquid Hydrogen at Temperatures below its Boiling Point on the Constant Volume Hydrogen and Helium Scales. By Morris W. Travers, D.Sc., Fellow of University College, London, George Senter, B.Sc., and Adrien Jaquerod, D.Sc. Communicated by Prof. William Ramsay, F.R.S.

Part i. (M. W. T. and A. J.).—The pressure coefficients were determined by measuring the pressure which the gases exerted when the bulb of the constant-volume thermometer was surrounded with melting ice, or with steam at the boiling point. The apparatus employed cannot be described in this abstract; it was completely constructed of soda-glass, and as all junctions were sealed in the blowpipe flame, leakage of the gas was impossible. By enclosing the manometer column and *dead space* between parallel glass plates in a water jacket, it was possible to measure the temperature of these parts of the apparatus to 0°·02 C. and thus eliminate errors which might seriously affect the results.

The pressure coefficient at an initial pressure of 700 millimetres in the case of either gas appears to have the value 0·00366255, which does not differ appreciably from that obtained by Chappuis for hydrogen at an initial pressure of 1000 millimetres of mercury. At a pressure of 520 millimetres no appreciable decrease in the value of the coefficient could be detected. As has hitherto been assumed, the pressure coefficient for hydrogen, and also for helium, appears to be independent of the pressure, so far as thermometric observations are concerned.

Part ii. (M. W. T., G. S. and A. J.).—Previous investigators have measured the boiling point and vapour pressures of liquid oxygen by immersing the thermometer in a mass of the liquid and measuring the pressure under which it was evaporating. This method is unsatisfactory on account of the difficulty of obtaining pure oxygen in sufficient quantity, and of the tendency of the liquid to become superheated.

In the experiments described in this paper, a bulb in which a small quantity of pure oxygen could be liquefied was immersed, together with the bulb of the thermometer, in a vacuum vessel containing liquid air or oxygen, through which a rapid current of air was passed. The bulb containing the pure oxygen communicated with the lower chamber of a barometer, so that measurements of the vapour pressures were quite independent of the atmospheric pressure.

Four thermometers were employed in these experiments, the capacities of the bulbs being approximately 90 c.c., 12 c.c., 26 c.c. and 27 c.c. The large thermometer was employed in one series of measurements only, as it was found to be difficult to maintain so large a bulb at a constant and definite temperature without employing very large quantities of liquid air. The temperatures obtained by means of the three smaller thermometers rarely differed by more than 0°·03 from the temperature, corresponding to the same pressure, taken from the smoothed vapour-pressure curve. The pressure on the gas at the ice point was in every case about 1000 mm. of mercury.

The thermometers were so constructed that the pressure on the gas could be measured independently of the atmospheric pressure. The temperature of the dead space was determined by means of a mercury thermometer, and the temperature of the vertical portion of the stem above the thermometer bulb was measured by means of an auxiliary gas thermometer, of similar construction, with a narrow cylindrical bulb of the same length as the stem. The coefficient of expansion of the glass was found to be 0·0000284 between 0° and 100° C., and 0·0000218 between 0° and −190° C.

Vapour Pressures of Liquid Oxygen.

Pressure in millimetres.	Temperature on hydrogen scale.	Temperature on helium scale.
800	90·60	90·70
760	90·10	90·20
700	89·33	89·43
600	87·91	88·01
500	86·29	86·39
400	84·39	84·49
300	82·09	82·19
200	79·07	79·17

Part iii. (M. W. T. and A. J.).—The three small thermometers used to measure the vapour pressures of liquid oxygen were also employed in the case of liquid hydrogen. The small bulb, which in the previous experiments had contained pure oxygen, now contained pure hydrogen. The agreement between the results obtained with different thermometers is indicated in the following table :—

I.—*Hydrogen Scale.*

Thermometer.	Vapour pressure of liquid hydrogen. mm.	Temperature. Found. °	Temperature. From curve.
A (12 c.c.)	757·2	20·17	20·21
B (26 c.c.)	766·6	20·28	20·25

II.—*Helium Scale.*

Thermometer.	Vapour pressure of liquid hydrogen. mm.	Temperature. Found. °	Temperature. From curve. °
A (12 c.c.)	765·0	20·42	20·44
,,	759·2	20·41	20·41
B (26 c.c.)	770·0	20·43	20·46
C (27 c.c.)	749·0	20·36	20·36

The vapour pressures were measured between the boiling and melting points. The results are as follows :—

Vapour Pressures of Liquid Hydrogen.

Pressure in millimetres.	Temperature on the hydrogen scale.	Temperature on the helium scale.
800	20·41	20·60
760	20·22	20·41
700	19·93	20·12
600	19·41	19·61
500	18·82	19·03
400	18·15	18·35
300	17·36	17·57
200	16·37	16·57
100	14·93	15·13
50	—	14·11

Though the pressure coefficients of hydrogen and helium between 0° and 100° C. show no appreciable difference, measurements of low temperatures on the scales of the two thermometers are not identical. It is probable that at the normal temperature both gases may be considered as so nearly perfect that the difference between the gas scale and the absolute scale is insignificant. As the critical point of helium lies much lower than that of hydrogen, measurements of low temperatures on the helium scale should approach more closely to absolute temperatures than measurements on the hydrogen scale. It is pointed out that helium should replace hydrogen as the normal thermometric substance.

The melting point of hydrogen was found to be 14°·10 on the helium scale.

The pure helium used in the thermometric measurements was obtained by passing purified cleveite gas through a coil cooled to 15° in liquid hydrogen boiling *in vacuo*. An unsuccessful attempt was made to liquefy this gas, which could not be condensed at 13° under a pressure of 60 atmospheres.

The vapour pressures of solid neon were measured at temperatures corresponding to 20°·4 (12·8 mm.) and 15°·65 (2·4 mm.). It was shown that the vapour pressure did not change as the solid evaporated, proving that neon is a homogeneous substance.

EDINBURGH.

Royal Society, July 21.—Prof. Geikie in the chair.—The Neill prize for 1898–1901 having been awarded to Dr. J. S. Flett for his papers entitled "The Old Red Sandstone of the Orkneys" and "The Trap Dykes of the Orkneys," Prof. Geikie, in making the award, recalled the important work which Dr. Flett had done in searching for and finding organic remains in rocks hitherto supposed to be unfossiliferous, and then in proving that these strata were divisible into definite zones, each characterised by its own particular fish faúna. The paper on the trap dykes could have been written only by one who was at once a skilled field geologist, a thoroughly equipped petrologist, an expert microscopist and a facile chemist.—In a further communication on magnetic shielding in hollow iron cylinders and superposed magnetic inductions in iron, Mr. James Russell discussed in particular the superposition of two magnetising forces at right angles to one another, and the magnetic æolotropy of demagnetised iron. Thus, if H_1 represent the field first acting and H_2 the field superposed at right angles to the first, and if B_1 and B_2 represent the resultant inductions in the directions of H_1 and H_2 respectively, then the general result was that with H_2 superposed on H_1 the B_1 component always lay above the B_2 component. For low fields the B_1 component is greater than in the normal case when no H_2 acts, but as the field is taken stronger the B_1 component approaches the normal value, and finally in high enough fields falls below it. The B_2 component lies below the normal value with this exception, that with low values of H_1 there is a slight excess of the B_2 component over the normal value. Then again, as regards æolotropy the following result was established. During the early stages of induction, iron is more permeable to a force in the same direction as that used in the immediately preceding process of demagnetising by reversals than it is to one at right angles to it. The results were discussed in terms of the recognised theories of molecular magnetism.—Dr. W. Peddie, in an additional note on the use of quaternions in the theory of screws, applied his method of interpretation to the case of a rigid body moving with two degrees of freedom, and was led to the investigation of the elliptic cylindroid, which differs from the ordinary cylindroid by being referred to an elliptic cylinder instead of to a right cylinder. Further developments were also given.—Prof. C. G. Knott read the second part of a paper on change of resistance of nickel due to magnetisation at different temperatures. The apparatus was the same as that already described, but by a modification in the method of experimenting more precise results had been obtained. The rate of change of resistance per unit increase of field at constant temperature and the rate of change per unit increase of temperature of this magnetic rate of change in a given field being distinguished as the magnetic change rate and the thermal variation respectively, the general conclusions were: (1) the magnetic change rate of resistance of a given nickel wire increases steadily with increase of field, but at a somewhat slower rate as the field increases; (2) the magnetic change rate increases slightly but unmistakably with rise of temperature up to 100° C. and probably higher; (3) the thermal variation of this change rate is greater at 40° than at 75° in fields higher than about 40, but tends to be less at the lower temperature in fields smaller than 35 or 40 C.G.S. units; (4) the change of resistance due to a field applied in a given direction is greater when the immediately preceding field has had the same direction than when it has had the opposite direction. The results were discussed along the lines of Prof. J. J. Thomson's theory of electrified corpuscles.—Prof. Alexander Smith, in continuation of a previous paper on the freezing point of sulphur, communicated a note on causes which determine the formation of amorphous sulphur. The proportion of amorphous sulphur formed in a mass of sulphur purified by crystallisation and kept heated at 448° C. was found to increase with the time which elapsed between the purification and the heating, and to decrease as the heating was greatly prolonged. Passing certain gases such as air, dry sulphur dioxide and dry hydrogen chloride through the sulphur during the heating increased the yield of amorphous sulphur; and under these conditions long continuation of the treatment did not cause any reduction in the yield. On the other hand, nitrogen, carbon dioxide, hydrogen sulphide and ammonia, used similarly from the beginning of the heating, seemed to prevent the formation of the amorphous form. It was not advisable to offer any theory until further work had been done.

PARIS.

Academy of Sciences, August 4.—M. Bouquet de la Grye in the chair.—Reflection and refraction as regards transparent bodies in rapid motion: reflected and refracted waves: amplitude of vibrations, by M. J. Boussinesq.—Experimental demonstration of the decomposition of carbon dioxide by leaves exposed to light, by MM. P. P. Dehérain and E. Demoussy. The authors point out that when the ordinary method of immersing leaves in a saturated solution of carbon dioxide is followed, the results are invariably successful with normally submerged aquatic plants like *Ceratophyllum submersum*, but vary greatly with plants the leaves of which normally decompose carbon dioxide in air. The results are satisfactory if the leaves

are placed in air above a saturated solution of carbon dioxide. The volume of oxygen liberated was invariably found to be exactly equal to that of the carbon dioxide decomposed, and no appreciable quantities of carbon monoxide, hydrogen, or gaseous hydrocarbons were formed.—The fruits of *Rosellinia necatrix*, by M. Ed. Prillieux. One of the common parasites which destroy the roots of fruit trees and vines was named *Dematophora necatrix* by Hartig, although he pointed out that it seemed to be closely allied to the group Rosellinia. The author has for the first time been able to study thoroughly the fruits, and as the parasite without doubt belongs to that group suggests a change of name.—Direct reduction of oxides of nitrogen by the contact method, by MM. Paul Sabatier and J. B. Senderens. A study has been made of the action of reduced nickel and reduced copper on the oxides of nitrogen. The results obtained are shown to be similar to those produced by spongy platinum, and it is pointed out that nickel or copper might with advantage replace platinum for such reactions.—Measurement of the limit of elasticity of metals, by M. Ch. Fremont.—On a new method of optically measuring the thickness of plates, by MM. J. Macé de Lepinay and H. Buisson (*cf. C. R.*, April 21). Results are given for a plate of quartz showing the great accuracy of the method.—Reflection of light from an iron mirror magnetised perpendicularly to the plane of incidence, by M. P. Camman. The author confirms experimentally the theory of M. C. H. Wind (*Archives néerlandaises*, 2e serie, t. i. 1897) regarding the reflection of light from magnetised mirrors, viz., if the incident light is polarised in the plane of incidence, the magnetisation has no effect upon the reflection, but if the incident ray is polarised perpendicularly to the plane of incidence, the time, the phase and the amplitude of reflected rays are changed.—Method of regulating resonators for high-frequency discharges with a view to their use in medicine, by M. H. Guilleminot.—On gentiobiose: preparation and properties of crystallised gentiobiose, by MM. Em. Bourquelot and H. Hérissey (*cf. C. R.*, cxxxii., March 4, 1901, p. 571).—Ammoniacal anhydrous copper chlorides: cupro-ammoniacal radicles, by M. Bouzat. The author finds that besides the compounds (*a*) $CuCl_2.6NH_3$ and (*c*) $CuCl_2.2NH_3$ described by Rose and Graham respectively, there is a third intermediate compound (*b*) $CuCl_2.4NH_3$. He assigns to them the constitutional formulæ

$$(a)\ \mathrm{Cu}\Big\langle\begin{matrix}\mathrm{NH_2}\\ \mathrm{NH_2}\end{matrix}\Big\rbrace 2\mathrm{HCl};\quad (b)\ \mathrm{Cu}\begin{matrix}\mathrm{NH(NH_4)}\\ \mathrm{NH(NH_4)}\end{matrix}\Big\rbrace 2\mathrm{HCl};$$

$$(c)\ \mathrm{Cu}\begin{matrix}\mathrm{N(NH_4)_2}\\ \mathrm{N(NH_4)_2}\end{matrix}\Big\rbrace 2\mathrm{HCl}.$$

—Action of nitrous acid in alkaline solution on α-substituted β-ketonic esters, by MM. Bouveault and René Locquin. The conclusion arrived at is that if the reaction is carried out under such conditions that the ester group is not saponified, or if it be saponified in acid solution, there results an acid and an oxime of a substituted glyoxylic ester; but if, during the reaction, the ester group is saponified in such a manner as to give the salt $\mathrm{R{-}CO{-}CH}\begin{matrix}\mathrm{COOMe}\\ \mathrm{R'}\end{matrix}$, one obtains a monoxime of an α-diketone and carbonic anhydride.—Antiparamœcious serum, by M. Ledoux-Lebard. The author finds that the serum of rabbits and guinea-pigs which have been several times injected with cultures of *Paramoecium caudatum* is much more toxic towards this species of Paramœcium than normal serum. The toxic effect is less towards other species of Paramœcium (*e.g. P. aurelia*).—Action of alcoholic fermentation on the *Bacillus typhosus* and the *Bacillus Coli*, by MM. E. Bodin and F. Pailheret. Alcoholic fermentation does not seem of itself to destroy these bacilli.—Variation of the phosphoric acid in cow's milk with time after calving, by MM. F. Bordas and Sig. de Raczkowski. The phosphoric acid diminishes steadily from the time of calving.—Researches on the assimilation of leaves, influenced by chlorophyll, of which the upper or lower surfaces may be exposed to light, by M. Ed. Griffon.—On the cavern of Holl-Loch (Hell's Cavern) and the Schleichende Brunnen (Creeping Springs), Switzerland, by M. E. A. Martel. This cavern, discovered in 1880, is one of the most remarkable in Europe. It lies near Stalden. A description is given.

NEW SOUTH WALES.

Linnean Society, June 25.—Mr. J. H. Maiden, president, in the chair.—By the wish of the council, the president explained to the meeting that, in consequence of the retrenchment policy which untoward circumstances had forced upon the neighbouring State of Queensland, it was to be feared that Mr. F. M. Bailey's "Queensland Flora," now in course of publication, would be brought to an abrupt termination in the middle of the sixth or concluding part. An expression of the views of scientific men in other States would perhaps help to justify the Queensland Government in making some special effort to utilise to the full Mr. Bailey's experience and unrivalled knowledge of the flora of Queensland in completing the important publication in question. On the motion of the president it was unanimously resolved, "That this meeting desires respectfully to give expression to the hope that, in the interests of science, the Queensland Government may see its way to allow Mr. F. M. Bailey to take the steps necessary to complete the 'Queensland Flora.'"—Notes on *Juncus holoschaenus*, R.Br., and *J. prismatocarpus*, R.Br., and on certain other New South Wales plants, by Mr. E. Cheel.—(1) On *Eucalyptus Baueriana*, Schau; (2) on *Eucalyptus calycogona*, Turcz, by Mr. J. H. Maiden.—A new gum (Levan) bacterium from a saccharose exudate of *Eucalyptus Stuartiana*, by Mr. R. Greig Smith.—*Eucalyptus melanophloia*, F.v.M., and its cognate species, by Mr. R. T. Baker. The object of the paper is to show that previous descriptions of this species must now be modified, as the foliage has not that constancy of form that has up to the present time been attributed to it.

A MONOGRAPH OF THE BRITISH LIVERWORTS.

The Hepaticae of the British Isles, being Figures and Descriptions of all Known British Species. By William Henry Pearson. Vol. i. text, vol ii. plates. Pp. vi + 520, and vii + plates 218. (London: Lovell Reeve and Co., Ltd., 1902.) Price 7*l.* 10*s.* net.

A TRUSTWORTHY work on the British Hepaticæ has long been needed by those who are interested in this somewhat difficult group of plants. Since the appearance of Sir W. J. Hooker's "British Jungermanniæ" in 1816, we have had no treatise on our native species that can be regarded as either up-to-date or as of much use to the student. A beginning was made some years ago by Dr. Carrington in cooperation with the author of the volumes before us, but, unfortunately, the attempt was not destined to meet with success, and the enterprise was abandoned at an early stage of its publication.

So many new forms have been added to the British flora since Hooker's time, partly as the result of revisions of older species and genera and partly owing to the discovery of new ones, that the whole subject has come to present a very different aspect from that which it wore ninety years ago. The vast majority of hepatics were then included in the single genus Jungermannia, whereas only comparatively few species are now retained in it. A more extensive study has gradually rendered it possible to segregate the species into smaller and more natural groups, such as are familiar to those who have been accustomed to use the well-known "Synopsis Hepaticarum" of Gottsche, Lindenburg, and Nees v. Esenbeck.

It is pleasing to remember that our own countryman Spruce, who added so much to our knowledge of liverworts, was one of the foremost to discriminate between, and give expression to, the affinities existing between the species of the larger and more complex genera. He was thus able to break up these unwieldy collocations of species into smaller and more manageable subgenera.

Mr. Pearson, in the fine work before us, has adhered to the general arrangement of Spruce as laid down by him in his "Hepaticæ Amazonicæ" and elsewhere, which has, with more or less modification, served as the basis for most of the modern forms of classification. The first volume is devoted to the text, and opens with an introductory chapter in which organography and other preliminary matters are very briefly dealt with. It is in connection with this chapter that we would express regret that Mr. Pearson should have allowed to slip by the opportunity of attempting some reform in the esoteric terminology that has grown up in association with this group of plants. Many terms possessing a perfectly well-known meaning in connection with the rest of the vegetable kingdom are, in the systematic literature of Hepaticæ, habitually distorted so as to imply something totally different from what they mean elsewhere. Thus the so-called stipules are not in the least degree comparable with stipules as generally understood, and the word ought to be altogether dropped in favour of *amphigastria*, a neutral term that may well be retained to designate the ventral leaves of these, usually dorsiventral, plants. The radially constructed species prove clearly enough that the amphigastria have nothing to do with true stipules, but are merely special leaves which owe their particular (often reduced) form to the dorsiventral habit of the stems. To continue to apply the older and misleading term of stipules to these structures is clearly an unjustified anachronism. Similarly, the expressions "Postical" and "Antical" might with advantage be replaced by the words Dorsal and Ventral, as universally used elsewhere. And once more, why continue to speak of "Pistillidia" instead of Archegonia, the word invariably employed in modern botanical works to designate these structures? Of course, Mr. Pearson is not to be held responsible for the introduction of these terms; they are of hoary, and we had hoped of senile, antiquity. And though he has probably retained them purposely, we could have wished that he had otherwise decided.

As regards the rest of the work, there is much deserving of praise. The descriptions of the species are clear and full, and the shorter notes that accompany many of them are interesting and often of critical value. Especially is this the case with species likely to be easily confounded. The special diagnostic characters are then discussed and emphasised, as, for example, in the two common species of Pellia, *P. calycina* and *P. epiphylla*. Curiously enough, however, no reference is made to the anatomical differences, pointed out by Leitgeb, between the cells of the thallus in these two plants. The geographical distribution of each species is mentioned, and frequently the actual localities also. Naturally these are not exhaustive, and those especially who have collected the plants in the more southern parts of England will be able readily to supplement them. Some species that are described as rather rare, *e.g. Reboulia hemispherica*, would probably not be so regarded by many people. A glossary, table of literature and a good index complete the volume. A chapter on the interesting biological features in which the liverworts are so exceptionally rich would have been a welcome addition to the book. There is hardly another family of plants that displays so manifold a variety of form or such a remarkable series of structural modification in relation to the environment as does that of the hepatics, and these fascinating adaptations deserve far more attention than they commonly receive.

The second volume is devoted to the figures, and it contains no fewer than 228 plates. These form a splendid adjunct to the text, and will prove of material service in the proper identification of the various species. The plates are in nearly all cases excellent, and each generally includes a life-size representation of the species, as well as drawings, on a large scale, of dissections, fructifications, &c. The cellular structure of the leaves is also depicted, and this will often be found of much value in deciding between doubtful cases. In the genus Fossombronia the spores are carefully drawn, as furnishing perhaps the most easily recognised characters by which the species of this somewhat difficult genus can be identified.

Although we have freely criticised certain features in the book wherein our own judgment happens not

altogether to have coincided with that of the author, we have done so feeling that to pass over these points of difference would be to pay Mr. Pearson but a poor compliment. For we fully recognise the great value of the work in all essential matters, and we cannot but admire the energy with which a task of no ordinary difficulty has been carried to completion. Mr. Pearson has laid British botanists under great obligations, and has succeeded in producing a book that ought to serve to rescue from comparative though altogether unmerited oblivion a family, by no means the least interesting, of the vegetable kingdom. J. B. FARMER.

STRUCTURALLY ACTIVE MEDIA.

De la Double Refraction elliptique et de la Tétraréfringence du Quartz dans le Voisinage de l'Axe. Par G. Quesneville. Pp. xiv + 361; avec 4 planches. (Paris: Gauthier-Villars et Fils, 1898.)

THE peculiar phenomena exhibited by quartz in directions slightly inclined to the optic axis were explained by Airy in 1831 on the hypothesis that in any such direction two streams of permanent type can be propagated, these streams being oppositely and elliptically polarised with their planes of maximum polarisation respectively parallel and perpendicular to the principal section. With the aid of these assumptions, he calculated the forms of the interference patterns displayed in plane and circularly polarised light by plates of quartz perpendicular to the optic axis, and also discussed the remarkable phenomena that are observed when two such plates of equal thickness but of opposite rotations are superposed and traversed by a convergent stream of polarised light that is subsequently analysed. The close agreement between these calculated results and the experimental forms of the curves led to a general acceptance of Airy's views, and the conviction of their correctness has since been strengthened by experimental investigations of a more direct character.

This theory M. Quesneville, without disguising the magnitude of the task, has undertaken to refute, replacing it by a new one devised by himself. He maintains that the interference exhibited by plates of quartz in polarised light is in at least one important particular at variance with the results calculated by Airy, and claims that Jamin's investigations (the only experiments that he discusses), so far from confirming the accepted theory, actually lend support to that which he himself enunciates. Further, he alleges a theoretical objection to Airy's hypotheses. According to these there is, of course, a continuous change in the polarisation of the waves of permanent type as the position of their normal changes from a direction inclined to the optic axis to that of the axis itself, while it is the circular polarisation, and not the rotary phenomenon, that is the fundamental property of an active crystal in this latter direction. M. Quesneville, however, contends that Airy's formulæ involve a discontinuity in the phenomenon, inasmuch as a rotation of the primitive plane of polarisation nowhere occurs therein, for "s'il existe suivant l'axe, il est inadmissible que tout près l'axe, alors que les ellipses sont presque des cercles, elle ait disparu."

This idea is the key-note of his own theory, according to which the streams in an active crystal, propagated in a direction slightly inclined to the optic axis, only become of permanent type after a certain zone has been traversed within which a rotation of the plane of polarisation is "le phénomène primordial." On entry into the crystal, a beam of plane polarised light is supposed to be resolved into two elliptically polarised streams of opposite sign with their planes of maximum polarisation respectively parallel and perpendicular to the primitive plane of polarisation; after a small distance has been traversed, these are regarded as having for their resultant a stream that is plane polarised in a new azimuth, while this is, again, equivalent to two fresh elliptically polarised streams; this process is supposed to continue during passage through the first zone, within which the elliptic vibrations change both in form and in orientation. It is not clear what circumstances determine the limitation of the zone, but it is assumed that after a certain length of path, that diminishes as its inclination to the axis increases, the two elliptically polarised streams cease to occasion a rotation of the last plane of polarisation, and that they then enter the second zone, where each gives rise to two streams of the permanent type assumed by Airy. In this manner the four-fold refraction of quartz in the vicinity of the axis is arrived at; there is, however, no assumption of more than two wave-velocities corresponding to a given direction, neither is there any recognition of a separation of the streams by refraction, so that the four elliptically polarised waves may be grouped together in pairs, the constituents of each group travelling with the same speed in the same direction, and there consequently is no question of a four-fold refraction, even if the author's contention be correct.

The limitation of this review precludes a discussion of the physical and mechanical difficulties involved in these ideas; they are, however, sufficiently obvious. It is claimed that the theory is not merely kinematical, but that it represents the actual state of things that occurs during the passage of light through a plate of quartz, though its author confesses his inability to formulate any hypothesis respecting the distribution of the ether round the axis of an active crystal from which it could be deduced.

The book in which this theory is expounded is divided into three sections, preceded by an introduction giving a sketch of the plan and scope of the work. In the first section the author discusses some investigations prior to his own. MacCullagh, in 1836, showed that the addition of certain terms to the differential equations of motion for inactive uniaxal crystals would lead to the elliptic polarisation assumed by Airy. Starting from a mistaken conception of the significance of these equations, M. Quesneville professes to show that "Convenablement interpretées," they prove that

> "Il existe dans le quartz une première zone pendant laquelle les rayons dès l'entrée donnent lieu à la rotation du plan primitif de polarisation, non seulement suivant l'axe, mais obliquement à l'axe jusqu'à la périphérie."

He then proceeds to a discussion of Jamin's experiments, deducing therefrom the result that in calculating the difference of phase between the two oppositely polarised

streams, introduced by passage through a plate of quartz, only the distance travelled in the second zone is to be taken into account. It may at once be conceded that Jamin's results do not afford a very striking confirmation of Airy's theory, which may in great measure be attributed to the experimental methods that he employed; but M. Quesneville in his criticism does not appear to have sufficiently recognised the distinction between the phase-difference of the streams on emergence into air and that of the rectangular plane polarised components of the resultant elliptically polarised train of waves.

In the second section we have the author's own experimental investigations, that were made with double prisms of quartz cut in different directions with respect to the optic axis and arranged in the shape of rectangular parallelopipeds. When the primitive polarisation is circular, M. Quesneville's theory leads to the same final results as that of Airy, but a divergence occurs when the initial polarisation is plane. Consequently it is found in accordance with both theories that if the light traverse the first prism along the optic axis and its path in the second be inclined to this direction, the emergent pencils can be completely quenched by means of a quarter-wave plate and an analyser; on the other hand, with a pair of prisms, such that the direction of propagation of the light was in the first perpendicular to the optic axis and in the second inclined to it at an angle varying from 5° to 9°, M. Quesneville was unable to obtain complete extinction of the emergent streams either with an analyser alone or with a quarter-wave plate and analyser, whatever might be their orientations. He thence deduced the inference that each pencil is formed of two elliptically polarised streams of opposite rotations that, having traversed the quartz with the same velocity, remain superposed on emergence, and on this experiment he relies for his proof of the four-fold refraction of quartz near the axis. It is noteworthy that this result was only obtained with small prisms, a fact for which a very inadequate explanation is offered.

The last section is devoted to a discussion of the rings produced by plates of quartz in polarised light. Two instances must suffice to show the manner in which Airy's formulæ are treated. On p. 280 it is argued that these would give the so-called quadratic curves even when the initial and final planes of polarisation are parallel, the fact being overlooked that the term that introduces this form of the curves has a factor that is then equal to zero; and on p. 341 the result that in the same circumstances the circles in white light would be black instead of coloured is deduced by equating to zero a sum of essentially positive terms. This section, however, contains several points of interest, the most important being the question whether or no circles exist in conjunction with the phenomenon known as Airy's spirals. In the photographs published in the book these circles do not appear, though they are present in those given by other authors. A question therefore arises as to the accuracy of the plates employed by M. Quesneville, but if his contention be proved it must be recollected that Airy's result is confessedly only approximate, and it is possible that a more complete investigation would lead to a formula giving spiral curves alone.

The book is wanting in the clearness of exposition that we are accustomed to expect from a French writer on a physical subject, and it is a matter for regret that the author, in his anxiety to make a strong case for his own views, should have permitted himself to repeatedly accuse Verdet and other physicists of "prudently passing over in silence" facts that tell against the theory that he is attacking.

ELEMENTARY PHYSICS.

A Text-book of Physics, with Sections on the Applications of Physics to Physiology and Medicine. By R. A. Lehfeldt, D.Sc. Pp. 304; 112 figures. (London: Edward Arnold, 1902.) Price 6s.

A COMPLETELY new arrangement has been adopted in this book in the order in which subjects are presented to the student. The traditional order of the text-book of physics has been abandoned, in many cases with advantage, but often a student will be sadly at loss in consequence. He will find it hard to fathom the object of proving (p. 81) that the elasticity of a gas is equal to its pressure before he is familiar with the idea of the elasticity of liquids (p. 85) or of solids (p. 130), and he can derive little help in his efforts by being given for the time being the definition of "constant ratio of stress to strain" when the immediate object is to prove that it is not constant, but equal to the variable p. The study of gases alone would never have suggested attaching importance to the ratio of stress to strain.

Again, to take another example, the subject order adopted involved introducing in connection with conductivity of heat (p. 72) the question of the anomalous expansion of water described later (p. 90).

Likewise, in treating of electrolysis (p. 188), the term electrical charge is used without explanation. In the order adopted this does not appear until p. 249.

Of course, it is not always possible to avoid such anticipations. Students often, however, in consequence fancy they do not understand the point in hand, when it is really the anticipation which is troubling them.

In the order of the chapters, "Heat" comes before "Properties of Fluids," and next comes "Properties of Solids." Sometimes the analogies adopted in consequence come quaintly to one accustomed to the old traditional order of things, and are apt to appear upside down, as the analogy taken from conductivity of heat to help the reader to grasp the idea of flow in liquids.

The work contains a vast number of distinct things for its size. Scarcely any branch of physics is omitted, but it is a question whether there is not too much in the book and whether less matter more carefully arranged would not have better chance of sticking. We must avoid giving our students mental indigestion from overloading. There is an unpleasant feeling throughout of being rather rushed, and that nothing must be left out which the external examiner may perchance alight on in setting the paper. Perhaps the fault, if it be one, may not lie with the book.

The attractions and repulsions of currents appear to be no further alluded to than in the statement describing the Kelvin current balances, that "of the two fixed coils on the right, one attracts the movable coil

near it, the other repels," leaving the reader to wonder why they do not both attract or do not both repel, or, indeed, why on earth they do either.

The plan of describing instruments and their working instead of the principles involved is to be deprecated in elementary text-books. At the very outset (p. 5) a description of how a tuning-fork is run by an electric current is given, with an explanation of the mode of action which, were it true, would mean that the vibration of the fork could not be kept up by the current. It seems unnecessary at the start to introduce the question at all, but if it must be so, the student should certainly be warned of the necessity of supposing some lag in the current.

One or two serious errors have crept in and must be altered in any future edition. In describing rigidity, the ordinary definition of a simple shear is given, but what follows will certainly bewilder the student.

"When a pair of steel shears or scissors is used, the force applied is distributed over a very small area, the area of the 'edge' of the shears, so that the shearing stress (per sq. cm.) is great, and the finer the edge the greater the stress becomes; consequently the material so stressed can be cut."

The area here spoken of is at right angles to the area meant in the definition, and in fact has nothing to do with the simple shear. Besides, the action in question is in reality anything but a simple shear.

Another passage requires rewriting. The air supplied to an organ pipe is spoken of as

"setting in motion a reed fixed in the end, or if there be none, the 'lip' or thin lamina of wood or metal near the front aperture of the pipe."

One misses the old familiar fundamental experiments of the text-books, and in many cases this absence is to be regretted. Thus, at p. 251, the attractions and repulsions of electrified bodies are not described as fundamental observations, but follow as corollaries in rather a cart before the horse fashion from the assumed shortening and swelling of things called lines of force. The student is given a picture of lines of force, and is told that it is "evident that positive and negative charges attract each other."

On p. 233 the metals have got evidently inverted, when it is said that "both soft iron and steel show retentivity, the former to even the greater extent of the two."

It is errors such as these which are just the ones which trouble the student.

From what has been said it might be inferred that the book was found to be without interest; such is not the case. With some alteration it is easy to imagine it made into a thoroughly useful one, especially for medical students, for whom it was more particularly written. The chapter on chemical physics is splendid and forms a most excellent introduction to the subject. The chapter on light is also good. Here the diopter system is introduced with effect; the parts touching on geometrical optics are simply described, no proofs being given. This has much to commend itself in a book of this scope, but at the same time the average student must not be asked to draw conclusions without being carefully given the premisses, as at p. 281, where he is told without further ado that "the distance B F is called the focal length and in case of a mirror is *clearly* half the radius of curvature." A first-class student will see there is something to prove and will prove it; others will not do either. This sort of thing tends in the long run to woolliness in thinking.

The book is well printed and the diagrams are good. There are few misprints; the following, however, were noticed and are given with the view of correction in a future edition. On p. 41, *l.* 32, heads should be altered to beads; p. 60, *l.* 21, 19°·57 to 195°·7; p. 78, *l.* 17, T to P; p. 141, *l.* 35, 0·93 to ·093; p. 267, *l.* 5, E to F.

On p. 180, *l.* 11, 48 watts per hour are spoken of; "per hour" should be omitted.

On p. 240 we find it stated that if a wire of length l be moved across a field of strength H, "the electromotive force due to a motion of 1 cm. will be proportional to lH"; "per sec." has dropped out.

THE VOICE AND RESPIRATION.

Health, Speech and Song: a Practical Guide to Voice-production. By Jutta Bell-Ranske. Pp. 158. (London: Swan Sonnenschein and Co., Ltd.; New York: E. P. Dutton and Co.) Price 4*s.* 6*d.* net.

ALTHOUGH the subtitle of this book is "A Practical guide to Voice-production," the space is chiefly occupied by a description of the organs of voice and respiration, accompanied by statements of the somewhat peculiar views of the author as to the anatomy and physiology of these organs, and criticisms of the views of the many schools of voice-production. There are but a few pages devoted to giving practical instructions on the training of the voice, and what little is said upon this subject is too vague and general to be of much service.

The book throughout is written in a very rhapsodical fashion, so much so that it becomes exceedingly difficult to trace out any meaning in some of its passages, while in other cases the effect produced can only be described as ludicrous.

The following passage may be cited as illustrating this:—

"Since I have stated that the vocal instrument consists of three elements, it might at first appear that each element must be of equal importance. And if the motor element which drives the organ were given us for the sole purpose of creating song, it would be so, but this element has a far more important function, being the element of life itself; hence song becomes only an overflow of life. Life is breath."

The author repeatedly deplores the ignorance of physiology shown by voice trainers, but the physiological statements made in the book are often very peculiar and occasionally erroneous. Thus it is stated on p. 27 that

"The diaphragm flattens, that is, is drawn down. The chest is expanded upwards, downwards and outwards, at the expense of the abdomen. The floating ribs, which are attached to the outer rim of the diaphragm, are pressed forward and outwards, thereby greatly expanding the bases of the lungs, an act which constitutes rib or costal breathing."

Other statements in the book (p. 28, *et seq.*) clearly show that the author confuses costal and diaphragmatic breathing, regarding these as identical and to be care-

fully distinguished from abdominal breathing, which is stigmatised as an exceedingly vicious process.

The description of the larynx and its muscles given in chapter iv. is very amusing to a person who is only acquainted with that organ as usually described. Thus, on p. 44, we are gravely told, though certain important intrinsic muscles of the larynx have been passed over without a word, that

"The only muscle that remains to be mentioned is the epiglottis, which is a thin, leaf-shaped cartilage that covers the aperture of the larynx when we eat, so as to prevent anything entering the voice-tube when food passes into the gullet (œsophagus)."

Many of the chapters in this novel scientific treatise are headed by beautiful quotations, such as

"He likened her voice to a string of pearls."

"And pure the pearls of matchless beauty they,
Yet purer still her song, for there was soul therein."

It may have been these quotations which suggested the statement to the author that song when not improved by development of the psychological side is a "pearl of value, but a *dead* jewel for all that."

The author deprecates the misunderstanding of psychology as it is used in voice-production; this arises, it is stated, from confusing its component parts, which are:—(1) Cognition—knowing; (2) volition—will; (3) feeling—affective states. Certainly there seems to us to be some ground for confusion here, especially as the author explains the matter no further, but simply leaves it thus.

In a chapter on deportment we are told that more than half the trouble existing around us springs from neglect of the diaphragm, and in this chapter also is found the remarkable statement that

"The contraction of the diaphragm flattens the abdomen, and invigorates all the various muscles that influence the liver and kidneys."

A very short chapter follows on "Advice to Singers," and the book then concludes with a recapitulation of the views of various authors as to the musical instrument which the voice most closely resembles.

B. MOORE.

OUR BOOK SHELF.

The Principles of Simple Photography. By F. W. Sparrow, R.N. Pp. 130. (London: Hazell, Watson and Viney, Ltd., 1902.) Price 1*s.* net.

THERE are now so many guides for beginners in photography that the first question with regard to a new one is as to the reason for its production. It is fitting that the author, who dates from H.M.S. *Royal Oak*, Mediterranean, should give a chapter on shipboard photography and hints for work abroad. This is evidently a description of the results of experience, and as such is a valuable record. It is, however, rather straining matters to suggest that differences of exposures of *six*, or even twenty, per cent. would make an appreciable difference in the result, even if it were possible to obtain plates of a uniformity of sensitiveness that would render such variations possible. The desirability of carrying plates rather than films is insisted on "for several reasons"; they can be obtained at almost any port of call, and on the whole are more trustworthy and more easy to work. The methods of extemporising a dark room on board ship are clearly described, and the apparatus in general and water supply are practically considered.

The other part of the book deals with apparatus, plates, exposure, development, printing, picture composition, &c., in very much the old-fashioned way. For development, pyro. and ammonia are prescribed, and the operation is either "normal," that is, rapid and risky, or "tentative," that is, slow, with the gradual addition of the accelerator. So long as the author follows the usual lines his information is trustworthy and useful, if not quite up to date; but when he departs therefrom he is not always a safe guide. The idea that "the perspective of a picture depends entirely on the focal length of the lens" is erroneous, though perhaps not original. There is confusion in the statement that a "very high tower with parallel sides" will show a convergence towards the top. We do not remember any guide to photography before this which states that the diaphragm cuts off the light that passes through the circumferential portions of the lens and thus gives the equivalent of a lens of smaller diameter; or that "chemical fog" (produced by unwise development) may be removed by an acidified alum clearing bath; that in fixing "the emulsion is eaten away from . . . the plate"; that a perfectly trustworthy method of intensification still remains to be discovered; that when varnishing, if the negative is made too warm the film will melt; that in modern printing out papers "the emulsion is composed of nitrate of silver—replaced by a chloride in toning—which is borne on a gelatine solution: hence the term gelatino-chloride paper"; that in many cases "hypo. is used to bleach the pulp" of which paper and mounting boards are made. Blemishes such as these enforce the opinion that, although this is one of the newest elementary guides for beginners in photography, it is not one of the best.

Philosophy of Conduct. By G. T. Ladd. Pp. xxii + 663 (London: Longmans, Green and Co., 1902.) Price 21*s.*

PROF. LADD'S remarkable industry is once more evinced by this bulky and comprehensive work on ethics. The general standpoint adopted, which will be already familiar to readers of other books by the same author, is that of idealist philosophy tempered by a strong interest in the facts and methods of psychology and anthropology. Prof. Ladd's latest work, while presenting a fairly complete survey of the facts of morality from this point of view, can hardly be said to add anything fresh to our comprehension of the theoretical and practical problems raised by the moral life. The author's arrangement of the subject-matter is perhaps adapted to be of service to students beginning a course in moral philosophy, though the connection he seeks to establish for it with the fundamental factors in psychological analysis seems forced. He treats first of the psychology of the moral life, the nature of the feelings of obligation and approbation, the origin and meaning of moral personality and moral freedom; next of the different types of action esteemed as virtuous or right by the moral judgment; and finally of the metaphysical implications of ethics and religion as held by believers in a personal absolute being. His treatment of the psychology of ethics, though largely acceptable to thinkers of all schools, suffers from a certain want of thoroughness and tendency to dogmatise. This is partly due to his habit of presupposing the results of his previous works on psychology. Now this would be a defensible plan of procedure if systematically followed, but it is at least tantalising to be offered lengthy disquisitions upon such all-important topics as moral freedom and personality, in which all the crucial positions are simply taken for granted. Prof. Ladd should either have dispensed with discussion at all or have made his discussions more thorough. Incidentally I may remark that the professor shows some acrimony in his treatment of opponents, frequently hinting that their opinions on the psychology and metaphysics of ethics are morally "dangerous," and now and then descending to the calling of names. There is a

particularly deplorable personal reference at p. 417 which might well have been spared.

The fundamental difficulty in the author's psychological theory is his ambiguous treatment of the self. He speaks of it, now as a product and process of development, in terms which seem to identify it with the moral character, again as a mysterious something behind character and acting causally upon it. The discussions of particular virtues in part ii., if somewhat too diffuse, are, to my mind, the most suggestive things in the whole book. In part iii. the attack on "utilitarianism" is too bitter to be discriminating. Egoistic Hedonism may be an illogical theory, but an egoistic Hedonist need not in practice be a worse man than his neighbours; it is mere vituperation to assert that "few prostitutes are so vile" as to be egoistic Hedonists.

The religious problems raised and in part treated by Prof. Ladd are too grave to be dealt with in a summary note like the present. A. E. T.

The Thompson Yates Laboratories Report. Edited by Rubert Boyce and C. S. Sherrington. Vol. iv., part i., 1901, and vol. iv., part ii., 1902. Pp. 563. (London: Longmans and Co.)

THE first ninety pages of part i. of this Report are occupied by a description of the filariæ or blood-worms obtained by the Liverpool Expedition to Nigeria. This practically constitutes a monograph upon this important group of parasites, is from the pen of Messrs. Annett, Dutton and Elliott, and a number of new species are described and illustrated. Dealing with human filariæ, the opinion is expressed that, notwithstanding certain differences between them, the weight of evidence is on the side of the identity of *Filaria nocturna* and *F. diurna*. The bibliography accompanying this paper should prove of the greatest value to future workers in the subject. The other important papers in part i. are the "Flora of the Conjunctiva in Health and Disease," by Dr. Griffith, and the use of bile-salt broth as a test for fæcal contamination, by Drs. MacConkey and Hill. The former gives a very complete account of the bacteriology of the conjunctival sac, and, like Lawson, Griffith has found the Xerosis bacillus to be a common inhabitant of the normal sac. In MacConkey and Hill's bile-salt broth we have a very useful medium for the detection of the *Bacillus coli* and allied species in water, but the procedure recommended, viz. to add 1 c.c. of the water to each of three tubes, would detect, in all probability, only a highly polluted water, not one in which the *B. coli* was present in small amount, in which case it is essential to concentrate the water by filtration through a porcelain filter and to examine the deposit. The same remarks apply to the examination of samples of the Liverpool water supply; the quantity of water examined (1 c.c.) is far too little to give a trustworthy negative result.

In part ii., Mr. Macdonald contributes an exhaustive paper upon the "Injury Current of Nerve," and Dr. Grünbaum and Prof. Sherrington make an important contribution to the physiology of the cerebral cortex in the higher apes. Dr. Annett produces some startling figures relative to the frequency of expectoration in public thoroughfares and the risk of infection with tuberculosis therefrom. The volume contains several other papers of minor importance upon various points of bacteriological, pathological and clinical interest, and concludes with the Report of the Liverpool Expedition to Brazil to study yellow fever, by Dr. Durham and the late Dr. Myers. The latter is somewhat disappointing, the ætiology of yellow fever being left very much where it was, save that a fine bacillus, difficult to stain and impossible to cultivate, was detected in the tissues.

In conclusion, it may be said that these volumes maintain in every respect the standard of their predecessors. R. T. H.

LETTERS TO THE EDITOR.

Sunset Effects.

AT Baveno (Lago Maggiore) on the evening of July 10, when the sun was setting behind the mountains in the north-western quarter of the horizon, a number of bright streaks of light appeared to radiate from behind a bank of clouds in exactly the opposite quarter of the sky. As these streaks were very bright near the point from which they apparently emanated and gradually faded away with increasing distance from that point, the effect was to produce the impression that the sun had set in the south-east instead of in the north-west. The explanation of the phenomenon is perfectly simple, being that the beams of sunlight, cut off by clouds and mountains, had travelled overhead through a clear atmosphere and, reaching the hazy air over the plains of Lombardy, had illuminated this air, which was especially thick at a point opposite the sun, the streaks appearing to converge to a vanishing point by the laws of perspective. The effect no doubt occurs whenever the necessary conditions prevail, viz., banks of clouds or mountains in the direction of the setting sun, a clear sky overhead and a thick atmosphere in the quarter opposite the sun.

G. H. BRYAN.

THE letter on iridescent sunset effects in the current number of NATURE (p. 370), and the correspondence now going on in the columns of *Science*, prompt me to send the following extract from my journal which was made on board the barquentine *Dayspring* while lying at anchor in Friday Island Passage, Torres Straits, on November 29, 1897:—

"The sun was setting behind cumulostratus clouds, while a little to the southward the horizon was occupied by a large storm cloud through which lightning was constantly playing, and other clouds of various types were scattered over the sky. Behind the storm cloud and between it and the sun were several very fine even-textured cirrostratus patches; these assumed *prismatic* coloration. The colours were very vivid and included the blues and greens as well as those of the red end of the spectrum; and they appeared to be arranged in the sequence of Newton's rings. The appearance of the clouds reminded me of a polarisation phenomenon. The colours were disposed in broad concentric bands shading into one another; they appeared to be dependent upon the *thickness* of the cloud mass, and were most brilliant at its thinner parts. The colours changed but slightly as the sun sank behind the horizon, but after a time the prismatic effect gave place to the ordinary sunset glow."

The phenomenon thus described made a great impression upon me at the time, and I am quite convinced that it had nothing in common with the normal "glow" reflected by the setting sun. S. PACE.

Hounslow, August 18.

THE OLDER CIVILISATION OF GREECE: FURTHER DISCOVERIES IN CRETE.[1]

IN a review of No. VI. of "The Annual of the British School at Athens," published last year (vol. lxiv. p. 11), the great importance of the discoveries of Mr. A. J. Evans at Knossos in Crete was pointed out, and the opinion was expressed that that volume contained "matter of extraordinary interest to students of the history, not only of Greece, of Egypt, and Western Asia, but also of mankind in general," for, since "the culture which now dominates the world is the child of the civilisation of Ancient Greece, . . . any archæological discovery which tends to increase our knowledge of the beginnings of Greek civilisation possesses an importance and an

[1] "The Annual of the British School at Athens." Part vii. Session 1900–1901. Pp. vii + 191. (London: Macmillan and Co., Ltd.)

interest far greater than that of any other possible discovery whatever in the archæological field." The writer then proceeded to sketch briefly the position of Mycenæan civilisation in history, insisting more especially upon what is now a commonplace of archæological knowledge—the fact that "the culture of classical Greece, as we know it, is but the second epoch of Greek civilisation. Classical Greece had a past, the true history of which had been half forgotten, had been preserved in confused and contradictory legends. The culture of the past had bloomed from end to end of the Greek world, in cities, some, like Athens or Knôssos, of renown in classical as well as præ-classical days, others, like Mycenæ and Tiryns, cities whose fame ceased to be when the Dorians entered Greece. This culture was bronze-using, and was, in fact, the Greek phase of the European culture of the Bronze Age, a phase earlier in date than the phases of Central and Northern Europe, and in all probability not only their forerunner, but to a great extent their forebear."

In Mycenæan discovery progress is swift, and the ideas of one year are never precisely those of the year before; and since these lines were penned the appearance of Prof. Ridgeway's "Early Age of Greece" has caused many defenders of the usual view to look well to their armour. For many weighty reasons which cannot be discussed here, it does not, however, seem probable that the view that the Mycenæan culture was not only the forerunner, but the forebear of the European culture of the Bronze Age, will be hastily abandoned in favour of the interesting theory propounded by Prof. Ridgeway. The discoveries of the last two years have pushed back the existence of human civilisation of the highest and most developed type in the Ægean basin to so remote a date B.C. that the possibility of this culture having derived its origin from Central Europe is fast fading away; it is to Egypt, if anywhere, that we must look for the first impulses of Ægean culture, and it is to this Ægean culture that we must look for the origins of the European civilisation of the Bronze Age. So that while it may be an exaggeration to say that the relation of the prehistoric civilisation of Greece to this general European culture is quite clear, it is none the less a mere affectation of reserve to imply that the nature of this relation is not, generally speaking, pretty clearly indicated by what evidence we have. The evidence points to the Ægean culture having been the forebear of the general European civilisation of the Bronze Age, of which it itself may be regarded as the Greek phase.

No dogma can be proclaimed as to the ethnic affinities of the people to whom this Ægean culture belonged. In "The Oldest Civilization of Greece," pp. 105, 202, the present writer has essayed the opinion that "the Mycenæan culture had well begun before the arrival of the Aryan Hellenes"; and we may, in fact, well hold that its originators belonged to that "Mediterranean Race" of Sergi, which extended from Armenia to Spain. When, however, the fair-haired invaders from the north—the "Celts" of Prof. Ridgeway—descended upon the Ægean world, it would seem that they took over the civilisation of their predecessors, over whom they henceforth ruled and with whom they mingled, while giving them their Aryan language. So it is that "the whole of Greek culture from the solid rock of the Athenian acropolis up" is indeed one, for the civilisation of the Aryanised "Hellene" was directly descended from that of the un-Aryan "Pelasgian" of Knossos or Phaistos without any "very violent break." Thus it is possible, without inconsistency, to write also that "the Mycenæan culture belonged primarily . . . to Hellenes," when one is not using the word "primarily" in the sense of time at all, and when, too, one has expressly, in order to make one's meaning clear even to the most careless critic, inserted between the words "primarily" and "to Hellenes" the sentence (in brackets) "*not entirely or necessarily originally*" ("Oldest Civilization of Greece," p. 104; not in italics in original). The sentence, "the Mycenæan culture belonged primarily (but not entirely or necessarily originally) to Hellenes" cannot be made to disagree with that previously quoted to the effect that "the Mycenæan culture had well begun before the arrival of the Aryan Hellenes," without suppressing the words within brackets, and thus suggesting a meaning for "primarily" not intended by the author.

The present writer holds, therefore, to his opinion, as expressed in "The Oldest Civilization of Greece," that the Ægean culture belonged originally to the præ-Hellenic race or races, but that in all probability some of its most important developments took place among populations already "Hellenised," *e.g.* in Argolis; *i.e.* it "belonged primarily to Hellenes." How far Cretan discovery may modify this position it is impossible as yet to say; in all probability, however, the modification will be in the direction of considerably reducing the probable connection of the Aryanised "Hellenes" (Achaians) with, at any rate, the Cretan monuments of the "Ægean" or early Mycenæan age, and in bringing the præ-Aryan, præ-Achaian population into greater prominence. Such a development has long been foretold by Prof. Ridgeway; but it is not probable that his drastic proposition "No 'Mycenæans' were Achaians" will ever be accepted in its entirety. To him, however, the inception of the idea is due; the point on which one would be inclined to criticise him is his proposition that the Pelasgians were Aryans, which, since the work of Kretschmer and Sergi has appeared, seems an old-fashioned view. Following Kretschmer, the present writer has maintained the view that the primitive population of the Ægean basin was of "kleinasiatisch" race, and that this race was not Aryan, since Lycian, the typical "kleinasiatisch" language, and its cognate idioms, Carian, &c., are obviously not Aryan, *pace* Prof. Bugge and one or two other Scandinavian philologists who still maintain the opposite view. In *Sphinx*, vol. ii. p. 120, the well-known veteran archæologist, Prof. Piehl, of Upsala, still holds the Scandinavian view, saying:

"Nous savons, grâce à Bugge, à Thomsen et à Torp, que cette langue [Lycian], très-vraisemblablement, est d'origine aryenne bien authentique."

With all respect to Prof. Piehl, it, however, must be recorded that, except in Scandinavia, Kretschmer's view seems to be now generally accepted, more especially since his philological results agree so remarkably well with those obtained by Sergi from craniological study.

We shall return to the question of race later; the above preliminary remarks are necessitated by the progress which has been made in Mycenæan study during the past year.

In the present number of the "Annual of the British School at Athens" Mr. Evans proceeds to describe the results of his further excavations at Knossos in 1901, when he was assisted by Dr. Duncan Mackenzie as excavator, and by Mr. D. T. Fyfe as architect. Mr. Fyfe has prepared the very clear and intelligible ground-plan of the palace which accompanies the memoir, and his services have no doubt been, generally speaking, of the greatest use to Mr. Evans, since nobody who has not visited Knossos can have much idea of the great amount of regular architectural, not to say engineering, work which has had to be carried out during the course of the excavations, consisting not only in the housing-over of the Throne Room (illustrated in NATURE, lxiv. p. 14, Fig. 4), but in excavating, shoring-up and underpinning staircases, remains of upper stories, &c., especially in the vicinity of the Hall of the Colonnades (Plan, G 10). Mr. Hogarth, who in 1900 excavated the town-ruins, did not work at Knossos in 1901, but transferred himself to the eastern end of Crete, where he worked on the

Mycenæan site at Zakro; his results are described in the present number of the "Annual."

The operations carried on at Knossos in 1901 are summarised by Mr. Evans on pp. 1, 2. Space forbids us to do more than select for description and discussion some of the more important results of his excavations.

The underlying Neolithic settlement was further investigated, and a report of the results obtained was made by Mr. Evans to the Anthropological Section of the British Association (Glasgow meeting, September, 1901; see NATURE, lxiv. p. 615).

The "Kaselles" (κασέλλαις), stone cists or receptacles beneath the floors of the Magazines (see NATURE, lxiv. p. 13, Fig. 2), have been proved to be chiefly safes for the keeping of treasure ("Annual," pp. 44 *ff.*).

The housing-over of the Throne Room has already been referred to. This work was urgently needed to protect the throne, &c., from the weather.

"In order to support the roof it was necessary to place some kind of pillars in the position formerly occupied by the Mycenæan columns, the burnt remains of which were found fixed in the sockets of the stone bench opposite the throne."

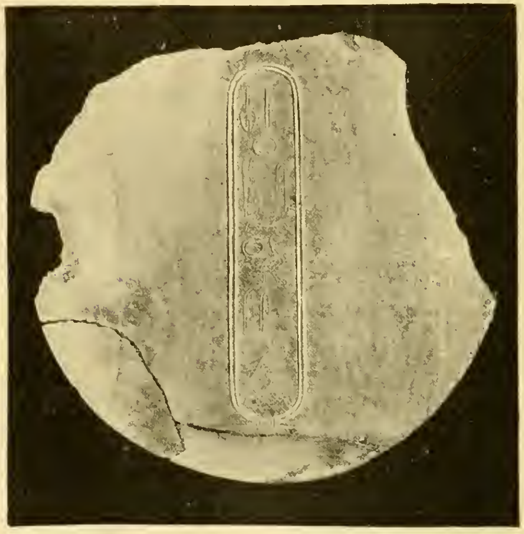

FIG. 1.—Egyptian alabastron-lid, inscribed with the name of the Hyksôs King Khyan (*c.* B.C. 1800) Found at Knossos.

Accordingly pillars of Mycenæan design were erected, and the whole roofed over. This necessary work of conservation is analogous to that at Dêr el-Báheri; no attempt at "restoration," as it is understood on the Continent, has been made. All who have seen the result can testify that it is entirely successful.

One of the chief results of the excavation is the inkling it gives of the great extent of the palace, which seems, in fact, to have not only covered the whole of the knoll on which it stands, but to have descended in a series of several-storied halls and towers down the eastern side of the hill to the bank of the stream which runs below. And now that Mr. Evans has announced the discovery at Knossos this year of contemporary representations of Mycenæan houses we may perhaps be able soon to acquire some idea of what the palace may have looked like when seen from the opposite eastern downs or from the way leading up from the sea. Mr. Fyfe's restored longitudinal section and plan (Fig. 33) give a very good idea of how the palace descended the eastern slope. On the left is seen one of the most sensational of Knossian discoveries, the quadruple staircase which descended from the Central Court to the Hall of the Colonnades, a hall which reminds one more of a court with *loggie* in an Italian palace than anything else! At the point of the staircase the palace was certainly three and probably four stories high; in fact, three flights of steps still remain. Originally the staircase "consisted of fifty-two stone steps, of which thirty-eight, and the indications of five more, are preserved." The excavation of the lowest flight "was of extraordinary difficulty, owing to the constant danger of bringing down the stairway above. It was altogether miner's work, necessitating a constant succession of wooden arches" (p. 104).

Down the greater part of this staircase it is now possible to walk, and in doing so the visitor gets a very good idea of the difficulties, already alluded to, which have beset Mr. Evans's work at Knossos, and of the successful way in which he has overcome them. But this heavy kind of work needs money, if it is to be properly carried out: the reader of NATURE who has a guinea or two to spare for archæological purposes could hardly do better than devote them to the Cretan Exploration Fund.

Mr. Evans is of opinion that "the whole result of the most recent excavations has been more and more to bring out the fact that, vast as is the area it embraces, the Palace of Knossos was originally devised on a single comprehensive plan. The ground scheme of a square building, with a central court approached at right angles by four main avenues, dividing the surrounding buildings into four quarters, is a simple conception which, as we now know, long before the days of the later Roman *Castra*, was carried out in the *Terremare* of Northern Italy. . . . The Minoan architect may claim the credit of adapting the same root idea to an organic whole, and fitting it in to a complicated arrangement of halls, chambers, galleries, and magazines, forming parts of a single building" (p. 100).

Further confirmation of the generally accepted date for the earlier parts of the palace, *c.* 1700 B.C. and later, was found in 1901 by the discovery in the "early Palace stratum," a deposit "containing a large proportion of charcoal, and representing the burnt remains of an earlier structure," and situated "immediately under the Mycenæan wall-foundations, at a depth of 40 centimetres below the later floor-level," of "the lid of an Egyptian alabastron, upon the upper face of which was finely engraved a cartouche containing the name and divine titles of the Hyksôs King Khyan" (see Fig. 1), who reigned somewhere about 1800 to 1700 B.C. The style of the hieroglyphs and phraseology of the inscription show us that this object is contemporary with the king whose name it bears. Therefore the discovery of this object of *c.* 1800–1700 B.C. may be taken to confirm the weaker evidence of the thirteenth dynasty statuette of Abnub, son of Sebek-user (date *c.* 2000 B.C.), which was discovered in the course of the excavations of 1900, and with this to indicate roughly the date of the beginnings of the great Palace of Knossos, which is undoubtedly, as its excavator maintains, the veritable Labyrinth of Minos.

The store of Knossian inscribed tablets has been largely increased during the course of the excavations; it is much to be regretted that the Cretan Assembly seems unable to see its way to allow any of these tablets to leave Crete for the purpose of study and possible interpretation.

Our knowledge of Mycenæan life has been increased in a rather startling way by the discovery of a fresco-painting depicting, side by side with the well-known "cowboys" of the common Mycenæan scenes of ταυροκαθάψια, of *female* toreadors in the act of tackling infuriated bulls. Mr. Evans remarks (p. 95):—

"The episode is sensational in the highest degree, but we have here nothing of the mere catching of bulls, wild or otherwise, as seen on the Vaphio Cups. The graceful forms and elegant attire of these female performers would be quite out of place in rock-set glens or woodland glades. They belong to the arena, and afford the clearest evidence that the lords of Mycenæan Knossos glutted their eyes with shows in which maidens as well as youths were trained to grapple with what was then regarded as the king of animals. The sports of the amphitheatre, which have never lost their hold on the Mediterranean world, may thus, in Crete at least, be traced back to prehistoric times. It may well be that, long before the days when enslaved barbarians were 'butchered to make a Roman holiday,' captives, perhaps of gentle blood, shared the same fate within sight of the 'House of Minos,' and that the legends of Athenian prisoners devoured by the Minotaur preserve a real tradition of these cruel sports."

The sinister impression which is given by this discovery is not dispelled by the sight of the deep walled pits, described by Mr. Evans on pp. 35, 36, which are, no doubt, as he says, the dungeons of the palace.

"In these deep pits with their slippery cemented sides above, the captives would be as secure as those 'beneath the leads' of Venice. The groans of these Minoan dungeons may well have found an echo in the tale of Theseus."

One is irresistibly reminded of Watts's picture in the Tate Gallery of the horrible Minotaur leaning over the high battlements of Knossos, looking out to sea, awaiting the bringing of his prey. The civilisation of Knossos was probably by no means Arcadian, even if it was Pelasgic!

The artistic triumphs of this Minoan civilisation are further established by the discoveries of 1901: *e.g.* the splendid vase illustrated on p. 91 (Fig. 30), the high reliefs in painted *gesso duro* (Figs. 6, 29, pp. 17, 89) which are so characteristic of Knossian art, the carved stone weight (Fig. 12, p. 42), &c.; an interesting hint of costume is given us in Fig. 17, a fresco-painting, presumably of a girl, whose coiffure is exactly parallel to that of the men from *Keftiu*, who are depicted in the Eighteenth Dynasty tomb of Rekhmarā at Thebes in Egypt; while the wonderful gaming-board of gold, ivory, crystal, and *kyanos* (Fig. 25, p. 79) tells us something of the minor amusements of the princes of Knossos. A curious find, "which strongly suggests a more seamy side of the high civilisation here represented," is that of "a clay matrix formed by making a stamp from the impression of an actual seal, and which could thus be itself used as a signet for making counterfeit impressions of the same kind. The original of this was evidently a large gold signet-ring of a kind resembling, both in its form and the character of its subject, that found in the Akropolis Treasure of Mycenæ. That this, like the other, was a royal signet is highly probable, and what adds to the interest of the matrix is that several clay impressions taken from the original ring were subsequently found in association with a very important deposit of inscribed clay tablets. . . . It would seem that the [counterfeit] clay matrix was actually used for forging the royal signature" (p. 19).

A rather startling discovery was that of a quantity of small bone objects, perhaps for inlay, many of which are inscribed with signs, among which occur most of the letters of the later Greek alphabet, though "the Mycenæan date of these bone pieces is as well ascertained as anything found within the walls of the palace" (p. 119). Here is an enigma.

It is a strange thing, this Cretan civilisation of perhaps the eighteenth to the fourteenth centuries B.C. Mycenæ we know, but this is not Mycenæ, though it is "Mycenæan." Knossos is older, and Knossos is more civilised. Knossos is no hill fort, ἐν μυχῷ, Ἄργεος, like Mycenæ or Midea; Tiryns is more like it. But Tiryns itself is strongly fortified with galleries and casements, which even now are wonderful; Knossos, however, seems open to the attack of any enemy. It seems a palace of secure peace, apparently undefended by walls, a palace of luxurious baths and polished dancing-floors, inhabited by princes who seem to have taken their pleasure in the leading of a life of luxurious ease, surrounded by a court of ladies in most amazingly modern low-necked dresses and coiffures like the triumphs of a Regent Street window, and men with hair as long as the women's and almost as elaborately dressed, served by crowds of slaves and tribute bearers, and diverted by the witnessing of brutal sports of the arena, in which women figured as well as men, sports connected possibly with the worship of a cruel deity to whom human sacrifice was not unknown, for whom, perhaps, were incarcerated the victims in the oubliettes, like the holes of the trap-door spider, which exist within the palace walls. Knossos was the seat of the just and mighty Minos: it was also the Labyrinth of the Minotaur.

This is conjecture, but it conveys the impression which Knossos, and also Phaistos and Gournia, give: an impression of an ancient culture, highly developed, peaceful, art-loving and luxurious, effeminate if you will; but brutal withal and possessing sinister traits which oppress the mind.

What overthrew it? What overwhelmed the City of Live-at-Ease with a storm of long-forgotten war, and burnt its halls and towers with fire? The conquering Aryan from the north, probably; but we do not know. Who the Minoans themselves were we hardly know. Dark Pelasgians, of Sergi's "Stirpe Mediterranea," speaking a language akin to that of the Lycians, most probably; identical with the *Keftiu* of the Egyptian tombs, there is no doubt. To one who has not made himself fully acquainted with the details of the subject the thought may occur that these *Keftiu* and the famous Youth with the Vase, or Cupbearer, from Knossos perhaps belonged to some intermediate race (in Northern Palestine, perhaps), which sent tribute on the one side to the dynasts of Knossos, on the other to Pharaoh of Egypt. Such an opinion is easily refuted, as follows:—The Cupbearer is Mycenæan in costume: so are all the other male figures at Knossos; Mycenæans like the men of the Vaphio Cups. And since Knossos was a "Mycenæan" town inhabited by Mycenæans, the probability is that the representations of Mycenæans upon its walls are representations of Cretan Mycenæans. And since it is not "alleged," but is a *fact* well known to all who have eyes to see, that the eighteenth dynasty representations of the *Keftiu* at Thebes are practically identical, even down to minute details of costume, with the Knossian Cupbearer, the natural conclusion is that these *Keftiu* were Cretan Mycenæans. The date thus indicated for the coming of Cretan ambassadors to Egypt is *c.* 1550 B.C. That they may have come from Knossos or Phaistos is by no means impossible.[1]

The excavations of Mr. Hogarth in a Mycenæan town

[1] In "The Oldest Civilization of Greece" the present writer has expressed the view that these *Keftiu* were more probably Cyprian than Cretan Mycenæans. The progress of discovery in Crete has, however, now convinced him that they were more probably Cretans.

at Zakro, on the eastern coast of Crete, identified by Spratt with the site of Itanos, described by him in pp. 121–149 of the "Annual," are of great importance, not only as giving us much new knowledge of Mycenæan house-building, but as throwing light upon the question of Mycenæan connections with Libya. The use of bricks for the upper courses of house-walls is now proved. The bricks were large and flat, the largest measuring 24 × 16 × 4 inches, and "well and squarely laid" (p. 130). In the houses, besides vases, bronze implements, &c., was found a large number (nearly 800) of clay sealings, bearing impressions of intaglios, three of which are figured by Mr. Hogarth (Fig. 45; see Fig. 2 below). These "Minotaur" types are in the highest degree curious. This female figure with a bull's head; this bull-headed woman with a bird's wings and tail—are they mere fanciful designs, or do they point to the veneration of some strange androgynous deity?

However late in the Mycenæan age the existing remains of the settlement may be placed, "*these were still anterior to the Age of Iron*," says Mr. Hogarth (italics in original). . . . "Nor were any fragments observed of distinctly geometric vases. . . . The fact that the remains . . . come to a clean and abrupt finish with" the close of the Bronze Age, "showing no admixture of remains of the succeeding epoch, is in favour of those who hold that the use of iron and the

FIG. 2.—Clay Seal. Impression from Zakro.

inception of the geometric style resulted from some violent and radical social change in the Ægean, such as conquest by a distinct race" (p. 146). Whether this was an Achaian or a Dorian conquest, Prof. Ridgeway and his critics must settle: personally, we still prefer the second alternative.

The settlement is regarded by Mr. Hogarth as a trading outpost of Knossos, and in view of the objects of Knossian type discovered, this view seems a very probable one.

"Its position," he says (p. 147), "indicates that Zakro traded with Libya direct, and not (as has been supposed) by a circuitous route through Rhodes and Cyprus." While still holding to his view that the circuitous route, by which we know came the great armament which attacked Egypt in Rameses III.'s time, in which it is possible that Cretan Axians were included,[1] was the most likely one for primitive navigators to follow, the present writer is inclined to think that he has, in "The Oldest Civilization of Greece," to some extent underestimated the possibility of direct communication in Mycenæan times between Crete and Libya. The bay of Zakro, remarks Mr. Hogarth (p. 123), "is the best known *rendezvous* and port of call for the fishing fleets of the eastern islands, which sail annually to the sponge-grounds off the Libyan shore. . . . For sailing craft the bay of Zakro is still the principal station on the road from the Ægean to Libya."

[1] It is true that Axos was an inland town but this was no bar to its having taken part in an over-sea expedition: see also Herodotos, iv. 154, which should not be forgotten.

The argument is a fair one, but we have no certainty that Mycenæan sailors were as familiar with the direct route to Africa as the modern sponge-fishers. The geographical objection to the theory of direct connection, which has been stated to be non-existent, is simply the absence of any coast leading the primitive voyager from Crete to Libya; he would naturally follow the coast round, as the later Greeks went from Greece to Sicily, and not sail south into an open and unknown sea. However this may be, space forbids the further discussion of the point here.

Mr. Hogarth appends a description by Dr. Boyd-Dawkins of proto-Mycenæan dolichocephalic skulls found by him, which the distinguished craniologist pronounces to possess characters which "point unmistakably to the fact that the possessors of the skulls . . . led the artificial life of highly civilised peoples" (p. 151). These skulls are regarded by him as belonging to the long-headed Pelasgic or Mediterranean stock of Sergi, which is what we should have expected.

The review of last year's "Annual" spoke of it as "the most important contribution to our knowledge of the early history of mankind that has appeared for many years" (NATURE, lxiv. p. 15). It can only be said of this year's number that in interest and importance it suffers very little by comparison with No. VI. H. H.

ALEXANDER KOWALEVSKY.

THE illustrious Russian embryologist and student of the anatomy of lower animal forms, Kowalevsky, died, to the great grief of the whole zoological world, on November 22, 1901, of an attack of apoplexy.

Kowalevsky was one of those rare men whose name is associated by all his contemporaries with a new departure in the branch of science which he cultivated. Albert Kölliker, still alive and well, had as long ago as 1844 followed with his microscope and drawn the division of the single cell constituting the egg of the cuttlefish, and had traced the process of the formation of the mass of embryo-cells by division of the cells resulting from the cleavage of the first or primary egg-cell. Remak, in 1850–58, had traced the evolution of definite tissues from the embryonic cells, and later students of the embryo chick had followed out the earlier indications of von Baer and were busy with the discussion of the origin and outcome of the embryonic layers of cells. But Kowalevsky went further than this, and in small transparent embryos (such as those of Ascidia, Amphioxus, Sagitta and Argiope) traced the history of adult organs cell by cell to the original egg-cell. It is this procedure which must immortalise Kowalevsky. Ten years after his first papers were published, the aim which he had given to embryological science became the definite and recognised purpose of successive generations of embryologists in England, Germany and the United States. Before Kowalevsky's work on the development of Amphioxus, carried out in 1864–65, and on Ascidia in 1866, zoologists were content to regard the cell-masses resulting from the first cell-divisions of the animal egg-cell as intricate heaps of units which no one could expect to analyse. Some way was made in the direction of their comprehension by the application to invertebrate embryos of the doctrine of cell-layers, but it was not until the avowed purpose of the embryologist became the definite tracing of the genesis of the cells of cell-layers one by one from pre-existing cells and finally from the first cell-divisions of the egg-cell that Kowalevsky's work bore its full fruit, and a thorough-going cellular embryology was established. Much still remains to be done on this basis, but we see it clearly foreshadowed in Kowalevsky's great memoirs on the development of Amphioxus and of Ascidia, wherein the identity of the nervous system, the

notochord, the alimentary canal and the primitive branchial slits of those two apparently unrelated animals is shown by the method of tracing the exact derivation of the cells constituting those organs in the two cases.

Kowalevsky published several embryological memoirs on Sagitta, Alcyonians, Holothurians, Argiope, Hydrophilus, Chiton and other forms, in which exact observation of the cell-lineage was his purpose and his result. His writings are singularly free from generalising theory; his delight and his power lay in the making and recording of exact observations destined to build up our understanding of animal structure on a sound basis. His later zoological researches included some minute studies on the anatomy of the vascular system in insects and some novel and important researches on the phagocytes of lower animals. He collaborated for a time with Marion, of Marseilles, and wrote with him on the Neomenians (Solenogastres). He was the discoverer of the planariform dwarf male of Bonellia, and was the first to describe the anatomy of the Balanoglossus of Della Chiaje and to demonstrate its perforate pharynx. In his last years he was occupied with researches on the structure of the leeches (especially the rare and extremely interesting setigerous leeches of the genus Acanthobdella) from Russian fresh waters, and on some other strange worm-like forms (the Hedylidæ) from the Sea of Marmora.

Alexander Onufrievitch Kowalevsky was born on November 20, 1840, in a country house situated not far from Witebsk, in the north-west of Russia. His father was a Pole and his mother a Russian. After his early education at home he was placed at the Engineering School of Roads and Highways at St. Petersburg. But he preferred the study of science to a practical career, and entered the faculty of natural sciences of the University. The University disturbances of 1861 obliged Alexander Kowalevsky to quit Russia and pursue his studies abroad. He went in the first instance to Heidelberg, where he was for some time a pupil of Bunsen. He actually published two small memoirs of a purely chemical nature under the guidance of the great German chemist. But very soon Kowalevsky's taste for zoology and comparative anatomy declared itself. After studying with Bronn and with Pagenstecker, Kowalevsky passed on to Tubingen, where he became the assiduous pupil of Leydig (still living and honoured in his old age). It is there that the young Russian learnt histological methods and prepared himself for his delicate researches on the anatomy and embryology of the lower animals. In 1864 he published in Russian his first zoological work, which was entitled "The Anatomy of Idothea." The paper contains anatomical details as to this Isopod, which is very common in the Bay of Finland. After having "passed his licentiate" (the equivalent of a bachelor's degree in England) at St. Petersburg, Kowalevsky went in 1864 to Naples with a definitely-thought-out programme of researches on the lower animals. He spent about eighteen months there (there was no Stazione Zoologica in those days), and it is there that he carried out his beautiful researches on the embryology of Amphioxus and of many other marine forms (Argiope, Sagitta, Holothurians, &c.), and also made his important discoveries as to the anatomy of Balanoglossus (revealing for the first time its curious branchial structure), which he subsequently published. In 1865 he had to return to St. Petersburg to pass his examination for the degree of "magister zoologiæ," and presented his memoir on Amphioxus as his inaugural thesis. He then returned to Naples, and at Ischia in 1866 he made his researches on the development of Ascidia, which he published in the course of the same year. It was this memoir, taken in conjunction with his similar discoveries with regard to Amphioxus, which startled the zoological world, led to the recognition of the Ascidians as Vertebrata, gave a new impulse and direction to embryological research, and among other things led to the development of the important doctrine of degeneration as applied to other than parasitic animals.

An epitome of Kowalevsky's researches on Ascidia and Amphioxus was written by Prof. Michael Foster at the request of the editors of the *Quarterly Journal of Microscopical Science* in 1870, and zoologists were divided into those who had and those who had not "bowed the knee to Kowalevsky." Kowalevsky, after being for a time "privat docent" at the University of St. Petersburg, was appointed professor extraordinarius at Kazan in 1868, professor ordinarius at Kiev in 1869, and at Odessa in 1874. He remained at Odessa until 1890, when he was made "titular member" of the Academy of Sciences of St. Petersburg. He was professor of histology during two years at the University of St. Petersburg, but later concentrated his activity on the Academy of Sciences and occupied himself much with the biological station at Sebastopol, of which he was director. Besides being a foreign member of the Royal Society, Kowalevsky was a member and correspondent of a great number of scientific academies, and was decorated by the Emperor of Germany with the order "pour le merite." He was married in 1868 and was the father of one son and two daughters. His son is a chemist, and one of his daughters (Madame Tchistovitch) is a doctor of medicine; the other is married to M. Cheviakoff. The celebrated mathematician Sophie Kowalevsky was the wife of a younger brother of Alexander Kowalevsky, the same who published some valuable work on mammalian palæontology about thirty years ago and died a few years later.

Personally Kowalevsky was a man of retiring disposition, devoted to his microscopic work, and of the most gentle and courteous address. He visited England with one of his daughters in October, 1895, for a few days, but took alarm at the dangers of the London streets and left somewhat abruptly.

The writer is indebted to his and Kowalevsky's friend, Prof. Elias Metschnikoff, of the Institut Pasteur, Paris, for the biographical details above given. Prof. Metschnikoff is preparing a biography of Kowalevsky for publication. A list of Kowalevsky's publications is given below.

E. RAY LANKESTER.

List of Papers by Alexander Onufrievitch Kowalevsky.

(1) Anatomy of the marine cockroach *Idothea entomon*, and list of the Crustacea which are met with in the freshwaters of the St. Petersburg Government. [In Russian.] (*Estest. izslyed. St. Petersb. ghub.* (*Russ. Entomol. Obshchest. S. Petersb.*), 1864, Tom. i).

(2) Le développement de l'*Amphioxus lanceolatus*. (*Archives Sci. Phys. Nat.*, xxvii. 1866, pp. 193–195; *Ann. Mag. Nat. Hist.*, xix. 1867, pp. 69–70; *St. Pétersb. Acad. Sci. Mém.*, xi. 1868, No. 4).

(3) Beiträge zur Anatomie und Entwickelungsgeschichte des *Loxosoma Neapolitanum*, sp. n. [1865.] (*St. Pétersb. Acad. Sci. Mém.*, x. 1867, No. 2).

(4) Anatomie des Balanoglossus, Delle Chiaje. [1866] (*St. Pétersb. Acad. Sci. Mém.*, x. 1867, No. 3; *Ann. Mag. Nat. Hist.* xx. 1867, pp. 230–232).

(5) Entwickelungsgeschichte der Rippenquallen. [1865.] (*St. Pétersb. Acad. Sci. Mém.*, x. 1867, No. 4; *Ann. Mag. Nat. Hist.*, xx. 1867, pp. 228–229).

(6) Entwickelungsgeschichte der einfachen Ascidien. [1866.] (*St. Pétersb. Acad. Sci. Mém.*, x. 1867, No. 15; *Quarterly Journ. Microsc. Sci*, x. 1870, pp. 59–69).

(7) Untersuchungen über die Entwickelung der Cœlenteraten. (Göttingen, *Nachrichten*, 1868, pp. 154–159).

(8) Beitrag zur Entwickelungsgeschichte der Tunicaten. (Göttingen, *Nachrichten*, 1868, pp. 401–415; Halle, *Zeitschr. Gesammt. Naturwiss.*, xxxii. 1868, pp. 343–344).

(9) Beiträge zur Entwickelungsgeschichte der Holothurien. [1866.] (*St. Pétersb. Acad. Sci. Mém.*, xi. 1868, No. 6).

(10) Die Entwickelungsgeschichte der Störe. [1869.] (*St. Petersb. Acad. Sci. Bull.*, xiv. 1870, col. 317–325; *Rev. Sci. Nat.*, 4, 1875–76, pp. 146–151).
(11) Weitere Studien über die Entwickelung der einfachen Ascidien. [1870.] (*Archiv. Mikrosk. Anat.*, vii. 1871, pp. 101–130).
(12) Embryologische Studien an Würmern und Arthropoden. [1869.] (*St. Petersb. Acad. Sci. Mém.*, xvi. 1871, No. 12).
(13) Ueber die Vermehrung der Seesterne durch Theilung und Knospung. (*Zeitschr. Wissensch. Zool.*, xxii. 1872, pp. 283–284).
(14) Zur Anatomie und Entwickelung von Thalassema. (*Zeitschr. Wissensch. Zool.*, xxii. 1872, p. 284).
(15) Ueber die geschlechtslose Fortpflanzung des Amaroecium. (*Zeitschr. Wissensch. Zool*, xx. 1872, p. 285).
(16) Ueber die Knospung der Ascidien. (*Archiv. Mikrosk. Anat.*, x. 1874, pp. 441–470).
(17) Sur le bourgeonnement du *Perophora listeri*, Wiegm. [Trad.] [1874.] (*Rev. Sci. Nat.*, iii. 1874–75, pp. 213–235).
(18) Ueber die Entwickelungsgeschichte der Pyrosoma. (*Archiv. Mikrosk. Anat.*, xi. 1875, pp. 597–635).
(19) Du développement des Actinies. [Trad.] [1875.] (*Rev. Sci. Nat.*, iv. 1875–76, pp. 15–26).
(20) Du mâle planariforme de la Bonélie. (*Rev. Sci. Nat.*, iv. 1875–76, pp. 313–320).
(21) Weitere Studien über die Entwickelungsgeschichte des *Amphioxus lanceolatus*, nebst einem Beitrage zur Homologie des Nervensystems der Würmer und Wirbelthiere. (*Archiv. Mikrosk. Anat.*, xiii. 1877, pp. 181–204).
(22) Ueber die Entwickelung der Chitonen. Vorläufige Mittheilung. (Carus, *Zool. Anzeiger*, ii. 1879, pp. 469–473).
(23) Zur Entwickelungsgeschichte der Alcyoniden *Sympodium coralloides*, M.-Edw., und *Clavularia crassa*, M.-Edw. (Carus, *Zool. Anzeiger*, ii. 1879, pp. 491–493).
(24) Weitere Studien über die Entwickelung der Chitonen. (Carus, *Zool. Anzeiger*, v. 1882, pp. 307–310).
(25) Observations on the Development of Brachiopods. [In Russian.] (Moscow, *Soc. Sci. Bull.*, xiv. 1874, pp. 1 (*bis*)–40 (*bis*)).—[Abstract.] (*Archives Zool. Expér.*, i. 1883, pp. 57–76).
(26) Note on the author's journey to the Caspian Sea. [In Russian, 1869.] (*Kiev Soc. Nat. Mém.*, i. 1870, pp. 19–20).
(27) Note on the structure of the alimentary canal in the Dendrocœla. [In Russian, 1869.] (*Kiev. Soc. Nat. Mém.*, i. 1870, pp. 109–110).
(28) Contribution to the embryology of the shark, from observations on *Mustelus laevis* and *Acanthias vulgaris*. [In Russian.] (*Kiev Soc. Nat. Mém.*, i. 1870, pp. 163–187).
(29) Development of the ova in *Sternaspis thalassemoides*, Otto. [In Russian.] (*Kiev Soc. Nat. Mém.*, i. 1870, pp. 287–290).
(30) Contribution to the embryology of *Amphioxus lanceolatus*. [In Russian.] (*Kiev Soc. Nat. Mém.*, i. 1870, pp. 327–338).
(31) Contribution to the embryology of the tortoise *Emys europaea*. [In Russian.] (*Kiev Soc. Nat. Mém.*, i. 1870, pp. 378–385).
(32) Preliminary report to the Society of Naturalists of the Vladimir University on measurements in the Black Sea. [In Russian.] (*Kiev Soc. Nat. Mém*, iii. 1873; *Proc.*, pp. 33–37).
(33) Observations on the development of the Cœlenterata. [In Russian.] (Moscow, *Soc. Sci. Bull.*, x. No. 2, 1874, pp. 1 (*bis*)–38 (*bis*)).
(34) *Neomenia gorgonophila*. [In Russian, 1880.] (Moscow, *Soc. Sci Bull.*, xxxvii. No. 1, 1881, pp. 181–186).
(35) Embryogénie du *Chiton polii*, Philippi, avec quelques remarques sur le développement des autres chitons. (*Marseille Mus. Ann.*, i. 1883, No. 5, 46 pp.).
(36) Étude sur l'embryogénie du Dentale. (*Marseille Mus. Ann.*, i. 1883, No. 7, 54 pp.).
(37) On the history of the development of the Chitons. Preliminary communication. [In Russian.] (*Zapīski Novoross. Obshchest. Estest. Odessa*, Tom. viii. pt. 1, 1882).
(38) On the preparation of the organs of some insects, spiders and centipedes. [In Russian.] (*Zapīski Novoross. Obshchest. Estest. Odessa*, xiv. pt. 2, 1889).
(39) Observations sur les organes excréteurs des animaux invertebrés. (*Zapīski Novoross. Obshchest. Estest. Odessa*, xiv. pt. 1, 1889).
(40) On the spleen of Mollusca. [In Russian.] (*Zapīski Novoross. Obshchest. Estest. Odessa*, xv. pt. 2, 1890).
(41) Ein Beitrag zur Kenntniss der excretionsorgane der Pantopoden. (*St. Petersb. Acad. Sci. Mém.* xxxviii. 1892, No. 12).
(42) Einige Beiträge zur Bildung des Mantels der Ascidien. (*St. Petersb. Acad. Sci. Mém.*, xxxviii. 1892, No. 10).
(43) Une nouvelle Glande lymphatique chez le Scorpion de l'Europe. (*St. Petersb. Acad. Sci. Mém.*, v. 1897, No. 10).
(44) Études anatomiques sur le genre Pseudovermis. (*St. Petersb. Acad. Sci. Mém.*, xii. 1901, No. 4).
(45) Phénomènes de la fécondation chez l'*Haementeria costata*, Müller. [In Russian.] (*St. Petersb. Acad. Sci. Mém.*, xi. 1901, No. 10).
(46) With Barrois (Jules), Matériaux pour servir à l'histoire de l'Anchinie. (Robin, *Journ. Anat.*, xix. 1883, pp. 1–23; *Ann. Mag. Nat. Hist.* xii. 1883, pp. 1–20).
(47) With Marion (A. F.), Études sur les Neomenia. [1881.] (Carus, *Zool. Anzeiger*, v. 1882, pp. 61–64).
(48) With Marion (A. F.), Sur le développement des Alcyonaires. (Paris, *Acad Sci. Compt. rend.*, xcv. 1882, pp. 562–565).
(49) With Marion (A. F.), Documents pour l'histoire embryogénique des Alcyonaires. (*Marseille Mus. Ann.*, i. 1883, No. 4, 50 pp.).
(50) With Marion (A. F.), Contributions à l'histoire des Solenogastres, on Aplacophores. (*Marseille Mus. Ann.*, iii. 1887, No. 1, pp. 76, 7 pls.).
(51) With Ovsyannikov (F. V.), Ueber das Centralnervensystem und das Gehörorgan der Cephalopoden. [1866.] (*St. Petersb. Acad. Sci. Mém.*, xi. 1868, No. 3).
(52) With Shulghīn (M. A.), Zur Entwickelungsgeschichte des Kaukasischen Scorpions, *Androctonus ornatus*. Preliminary communication. [In Russian.] (*Zapīski Novoross. Obshchest. Estest. Odessa*, xi. pt. 1, 1866, pp. 39–55).

And quite recent papers on leeches (Acanthobdellidæ) and on the curious worm-like Gastropods, the Hedylidæ of the Sea of Marmora and Black Sea, published in the *Transactions* of the Imperial Academy of Sciences of St. Petersburg (the latter since his death).

NOTES.

THE Berlin official *Reichsanzeiger* announces that the order "Pour le Merite" has been conferred upon Lord Avebury and Prof. A. Agassiz, of Harvard University.

THE Hugh Miller centenary will be celebrated at Cromarty to-morrow, August 22. At the public meeting addresses will be given by Mr. Arthur Bignold, M.P. (chairman), Sir Archibald Geikie, F.R.S., the Right Hon. James Bryce, M.P., Principal Rainy, D.D., and Prof. J. M. Clarke, of Albany, New York.

THE *Daily Mail* reports that millions of winged ants descended on the Bohemian watering-place of Teplitz in a dense cloud on Saturday, August 16. At Brussels also there were swarms of ants, and the streets in some places were so thickly strewn with their bodies that the firemen had to be called out to wash them away.

A REUTER message from Yokohama states that the small island of Tori Shima, which is one of a chain extending between the Bonin Islands and the main island of Japan, was overwhelmed by a volcanic eruption between August 13 and August 15. There were about 150 inhabitants, and the whole of them appear to have perished. The island is covered with volcanic débris and all the houses have disappeared. The eruption was still proceeding on August 18, together with a submarine eruption in the vicinity of the island, and passing vessels report that the place is dangerous of approach.

THE manager of the Eastern Extension, Australasia and China Telegraph Company sends us the following extract from a letter received from the superintendent at Banyuvangi, Java, dated July 6:—"The Rooang volcano, which is about thirty-five miles from

Banyuvangi to the west, and has the appearance of being much closer, is, as a rule, very quiescent, only a very slight column of smoke being visible. On May 1 it commenced to throw up large columns alternately of black and white cloud, the whole mountain being at times quite hidden with the cloud. This continued until May 4, when it again assumed its usual peaceful appearance. It is curious that this should have occurred about the same time as the big affair in the West Indies." Since about the end of April, reports of volcanic eruptions, earthquakes and other disturbances apparently connected with them have been received almost every day. It is suggested by the *Newcastle Daily Chronicle* that the numerous colliery explosions which have recently been recorded may have some relationship with the seismic disturbances, and that a commission should be appointed to bring together the records of eruptions and earthquakes with a view to determine whether they have any connection with the occurrence of explosions in coal mines. Whatever may be the result of such an inquiry, there are many indications that the present year is an abnormal one in several respects.

THE death is announced, from Vienna, of Dr. Leopold Schenk, formerly professor of embryology and author of a work on the artificial determination of sex by means of diet.

A REUTER message from Bulawayo states that further discoveries have been made in the great ruins at Zimbabye. Two ancient ascents leading up to the citadel have been found, and the citadel itself has been cleared. An old stairway was also discovered, and various objects, including gold bangles and pieces of pottery, were found. One of the passages which was penetrated for the first time is 994 feet in length.

WE learn from the *Times* that Prof. Barbosa Rodrigues, director of the Botanical Garden of Rio de Janeiro, has arrived in England on a short visit. The Brazilian Congress has voted a considerable sum for the printing of his work "Sertum Palmarum," in which he describes 160 species of palm trees, entirely new and discovered by himself in his journeys in the interior of Brazil for more than thirty years, the letterpress to be accompanied by large coloured plates drawn in the places where each species grows spontaneously.

SOME time ago it was decided by some of Mr. Nicholson's friends and colleagues to offer him, privately, on the occasion of his retirement from the Curatorship of the Royal Gardens, Kew, some tangible evidence of the high regard in which he is held. We now learn from the *Gardeners' Chronicle* that the committee formed to carry out the proposal received contributions sufficient to purchase several articles to remind Mr. Nicholson of his old friends, among them being a salver bearing this inscription:—"Presented to George Nicholson, V.M.H., late Curator of the Royal Gardens, Kew, by his friends and colleagues, who, while admiring his qualifications as a man of science and a gardener, have a warm appreciation of his worth as a friend. 1902."

The *Times* announces that the following prizes have been awarded for essays on subjects connected with tropical diseases:—(1) A prize of the value of 10*l*., entitled the Sivewright prize, presented by Sir James Sivewright for the best article on "The Duration of the Latency of Malaria after Primary Infection, as proved by Tertian or Quartan Periodicity or Demonstration of the Parasite in the Blood," awarded to Dr. Attilio Caccini, assistant physician, Hospital of Santo Spirito in Sassia, Rome. (2) A prize of the value of 10*l*., entitled the Belilios prize, presented by the Hon. E. R. Belilios, C.M.G., for the best article on "The Spread of Plague from Rat to Rat, and from Rat to Man by the Rat-flea," awarded to Dr. Bruno Galli-Valerio, professor in the University of Lausanne, Switzerland. The prize of the value of 10*l*. entitled the Lady Macgregor prize, presented by Lady Macgregor for the best article on "The best Method of the Administration of Quinine as a Preventive of Malarial Fever," was not awarded. The judges were Surgeon-General Roe Hooper, president Medical Board, India Office, Colonel Kenneth MacLeod and Mr. Patrick Manson, F.R.S.

AT the forthcoming meeting of the British Association the address of the president of the Section of Anthropology, Dr. A. C. Haddon, F.R.S., will deal with the wide subject of totemism, and may be expected to lead to discussion; other folklore papers are offered by Mr. T. N. Annandale, on the popular religion of the Malays of Patani; by Rev. J. H. Holmes, on the religious ideas and initiation ceremonies of the natives of the Papuan Gulf; by Mr. E. S. Hartland, on the stone of destiny at Jara, and the appointment of a king by augury; and by Mr. F. T. Elworthy, on perforated amulets. Archæology, especially British, will be well represented. Mr. W. J. Knowles has a paper on plateau-implements from interglacial gravels, and a series of exhibits illustrating the manufacture of stone implements; Miss Layard describes a new Palæolithic site at Ipswich; Messrs. Clinch, Fennell and MacRitchie discuss the significance of British underground dwellings of Neolithic and later periods; and Mr. Coffey describes the Irish equivalents of the Hallstatt period of culture, in relation to the introduction of iron in western Europe. There is an important paper on the types of British Neolithic pottery by the Hon. John Abercromby, and a full report of this year's excavations at Silchester and in Crete. Physical anthropology will be represented only by Prof. D. J. Cunningham's paper on the Irish giant, whose skeleton will be present, and by a few minor exhibits of an anatomical kind; but there will be several important papers in descriptive ethnography; on the Lolos of Szechuan, by Mr. Augustine Henry; on the Nagas, by Dr. Furness, of Philadelphia; and on the races of the Malay Peninsula, by Messrs. Annandale and Robinson. A paper by Dr. Graham on the mental and moral characteristics of the people of Ulster is likely to lead to some discussion. Important reports will be presented by the committees on the age of stone circles, on Canadian ethnography, and on the teaching of anthropology in Great Britain and elsewhere.

WE are glad to note the formation of an Imperial Vaccination League. The Vaccination Act of 1898 will expire at the end of 1903, and from this it follows that legislation of some kind will be necessary next year. The League desires mainly to assist the community to study carefully certain possible amendments of the 1898 Act. Foremost of these is the necessity for obligatory revaccination of school children at a specified age. This practice is universal in Germany, and to it the freedom of that country in recent years from epidemic small-pox must be assigned. The League will also consider the question whether the entire supply of glycerinated calf-lymph should not be guaranteed and regulated by some public authority. In Germany fifty-five millions of people are supplied by twenty-two State laboratories; Great Britain and Ireland, with forty millions of people, have but one. The League intends to put its views upon these subjects before members of both Houses of Parliament and to circulate literature. For this purpose it appeals for funds, which may be sent *inter alia* to Dr. Edwardes, at the offices, 53 Berners Street, W.

AN interesting address was given by Sir James Crichton Browne, the president of the Sanitary Inspectors' Association assembled last week at Middlesbrough. Sir James referred to the *rôle* played by flies in the propagation of disease. Leaving aside the researches concerning the part played by the Anopheles in malarial infection, he confined his attention to the common house-fly. "This most fearless and audacious of all creatures" is probably the carrier of many varieties of bacterial infection.

It appears that cultures of many pathogenic organisms have been obtained recently from the excreta of the common house-fly, *Musca domestica*. The *rôle* played by these insects in the dissemination of enteric fever in South Africa was referred to, and Sir James remarked that one of the collateral advantages of our campaign in South Africa might prove to be the opening of our eyes to the part played by flies as disease mongers. The enormous fertility of the ordinary fly forms one of the chief obstacles to its extermination; it has been calculated that one female fly may have 25,000,000 descendants during one season.

MESSRS. COOK, the tourist agents, have put forward a proposal to run an electric railway to the crater of Vesuvius from the Naval Arsenal in Naples to take the place of the funicular railway now used. The Faculty of Science in the University of Naples has forwarded a strong protest against the scheme to the Italian Government, on the grounds that it would interfere with the seismic and magnetic observations and records which are made at the University.

THE lecture delivered by Mr. J. Swinburne before the Incorporated Gas Institute, on the electrolysis of gas mains, is a valuable and impartial *résumé* of the whole subject. Few will disagree with the conclusion that the question is not really settled, and that although electrolysis undoubtedly takes place it is hardly possible at present to say whether it is serious or not. Mr. Swinburne urges the gas and water companies to watch carefully; should serious corrosion be observed some means must be found of making those who are responsible pay for the damage, though it is to be feared there will be difficulty in fixing the responsibility in towns, such as London, where there are a number of electric tramways and railways. The lecture is reprinted in the last two issues of the *Electrician*.

IT is proposed to work electrically that part of the New York Central Railway which runs through the city, the principal motive for the conversion lying in the fact that two miles of the track are in a tunnel. The scheme involves the electrification of thirty miles of track, at a cost of nearly three million pounds, and requires a power station with an output of 100,000 h.p. As a result of tests with a dynamometer car on a portion of the lines, estimates of the cost of working with different electrical systems have been prepared. These are embodied in a paper read by Mr. D. J. Arnold before the American Institution of Electrical Engineers. Local conditions have largely determined what system should be recommended, and that which works out cheapest has in consequence not been chosen. The one selected comprises a combined alternating- and direct-current generating station near the outer end of the line and a substation at the other end, with batteries in both. The alternate-current transmission is at 11,000 volts and the direct-current working pressure is 600 volts. The total cost with this system is estimated at 23·63 cents per locomotive-mile as against 24·18 cents with steam. The economy is little enough, and would not be sufficient to justify the conversion unless there were other considerations. The *Electrician* justly points out that the scheme, if adopted, can hardly fail to be merely the stepping-stone to the complete conversion of the whole railway.

A PAPER has been contributed to the Lombardy *Rendiconti*, xxxv. 15, by Dr. Edoardo Bonardi, in which the author asserts his disbelief in the existence of specific characters in bacteria, and considers that a curative serum has no rigorously specific action, but that its action in curing infectious diseases consists in its strengthening the animal organism against the attacks of disease germs.

FROM Prof. Garbasso we have received the reprint of a note communicated to the *Atti* of the Italian Electrotechnical Association on the condition under which two conductors arranged in multiple arc are equivalent to a single conductor when self- and mutual-induction are taken into account. A more general discussion of the discharge of a condenser by n wires arranged in parallel is given by the same author in the *Annalen der Physik*, 8.

IN acoustics it is common to measure large intervals of pitch in octaves and smaller ones in "commas." M. A. Guillemin proposes to adopt instead of these units the *savart* and the *millisavart*. By the savart is meant an interval of ten to one, which equals three octaves plus a major third. The millisavart, which is the thousandth part of the savart, represents the interval between two French standard diapasons giving one beat per second.

WE have received a reprint from the *Astronomical Journal*, for January, of Dr. G. Johnstone Stoney's paper on the effect of meteoric deposits on the length of the terrestrial day. It deals exclusively with the effects so far as they are due to an alteration of the moment of inertia of the earth, the object being to show that when the earth's compressibility is taken into account the increase in the moment of inertia is much smaller than would appear from calculations in which this influence is omitted.

IN a preliminary note contributed to the *Atti dei Lincei*, 9, Dr. Quirino Majorana describes certain novel magneto-optic phenomena. The analogy of Kerr's phenomenon has suggested that when a substance possessing magnetic properties is placed in a field of force, the state of strain set up should give rise to double refraction. Dr. Majorana has investigated this magnetic double refraction, which he finds exists in a small degree in ferrous chloride and to a greater extent in dialysed iron or ferric oxide in colloidal suspension. But another phenomenon was observed, particularly in solutions of ferric chloride that had acted on hydrates of iron. This phenomenon consisted in a rotation of the plane of polarisation when this plane was neither parallel nor normal to the lines of force. In each case the direction of the incident light was perpendicular to the lines of force, and if the direction of polarisation was either parallel to or perpendicular to the lines of force, no phenomenon of the kind considered was observed, while, on the other hand, the effect was a maximum when the direction of polarisation made an angle of 45° with these lines, and it consisted in a rotation of the plane of polarisation which the author describes as positive when its direction is towards the lines of force. For this phenomenon the name of bimagnetic rotation is proposed.

THE report of the director of the Liverpool Observatory for the year 1901 has been published, by order of the Mersey Docks and Harbour Board, and contains the usual daily results of meteorological and other observations, which are the more valuable from the fact that they have been continued and carefully prepared for a long series of years. The Observatory lies within the area of the usual tracks of our prevalent westerly gales, and this is doubtless one reason for the special attention that is given to wind observations; these embrace anemometrical records of the horizontal motion of the air and the extreme pressure on the square foot. In addition, the tables show the maximum daily velocities recorded on a Dines's pressure-tube anemometer, and thus afford a valuable check on the registrations of the ordinary instruments. In addition, to the regular work of a first-class observatory we observe that telegrams are forwarded daily to the Meteorological Office for use in the preparation of weather-forecasts and storm-warnings, and that special observations of clouds are supplied in connection with the monthly international balloon ascents, which are frequently noticed in our columns. The earth disturbances that have been registered during the year have also been carefully collated.

WE have received vol. xliii. part 2 of the *Annals* of the Astronomical Observatory of Harvard College, containing observations and investigations made at the Blue Hill Meteorological Observatory at Massachusetts in the years 1899 and 1900 under the direction of Dr. A. Lawrence Rotch. The first five tables include the observations made twice daily, together with summaries of them both at the base and valley stations, and a summary of visibility of objects in different azimuths; all these refer to the year 1899, while similar information is brought together in tables vi. to x. for the year 1900. Tables xi. to xiii. give general summaries for the lustrum 1896–1900, and table xiv. is devoted to phenomena which show the advance of the seasons for the 15 years 1886–1900. Appendix A. contains a very interesting study of the visibility of distant objects 18 to 40 miles away in different azimuths, based on observations made during the years 1896–1900. A very valuable series (1851–1900) of temperature observations made at Milton is discussed in Appendix B.

IN No. 3 of vol. ii. of the *Journal of Hygiene*, Dr. Ritchie continues his interesting *résumé* of "Current Theories on Immunity." Mr. Irons discusses the value of neutral-red in water-examination, and concludes that used alone this method is likely to give misleading results. Dr. Savage, in an interesting paper on the presence of the *Bacillus coli* in drinking waters, gives some useful data for estimating the significance to be attached to this organism. Post-scarlatinal diphtheria is dealt with by Dr. Pugh in an exhaustive paper; vital statistics are represented by Dr. Hayward, who writes on the construction and use of life-tables; and the diseases of tropical countries are dealt with by Major Aldridge, R.A.M.C., and Dr. Stanley, who contribute papers on "Enteric Fever and Sewage Disposal" and on "Beri-Beri" respectively, and the number concludes with an obituary notice on Dr. Thurburn Manson. Every number of this comparatively young journal hitherto published covers a wide field and contains many valuable contributions.

HAVING regard to the varied opinions that have been expressed relative to the thermal death point of the tubercle bacillus in milk (see NATURE, vol. lxiii. pp. 166, 205 and 353), a paper by Mr. H. L. Russell (*Philad. Med. Journ.*, November 16, 1901) on bovine tuberculosis and milk supplies is worthy of note. Milk was infected with tubercle bacilli from cultures and was then pasteurised in a rotating commercial pasteuriser, and after treatment the milk was tested by inoculation. It was found that even a ten-minutes' exposure at 60° C. was sufficient to destroy the vitality of the tubercle bacillus so thoroughly that no trace of disease developed in the inoculated animals. In an open vessel, however, a fifteen minutes' exposure had no effect. This difference seems to be due to the film which is formed when milk is heated in an open vessel. Provided the pasteuriser be closed so that no film forms, a temperature of 60° C. acting for not less than ten minutes, preferably for 20–30 minutes, is sufficient to destroy the infective properties of tuberculous milk, while such treatment hardly alters the flavour and nutritive qualities.

THE voluminous reports annually issued by the various experimental stations as well as by the central Government are proofs of the fostering care exercised by the State for agriculture in the United States. In an excerpt from the "Eighteenth Annual Report of the Wisconsin Agricultural Experimental Station," 1901, which has recently reached us, among other valuable papers is one by Messrs. Babcock and Russell upon the "Causes Operative in the Formation of Silage," and the view is expressed that the changes which lead to silage production are hardly explicable on the theory that these are caused by the growth of micro-organisms, but rather that the internal processes of the living plant cells themselves are the factors which inaugurate the series of changes that result in the formation of typical silage.

TO the July number of the *New Phytologist*, Prof. F. W. Oliver contributes an article on "Gymnospermous Seeds," in which he traces a suggestive connection, possibly phylogenetic, between the fossil types Lagenostoma and Pachytesta and the existing genus Torreya. The examination of rhizomic material of the unique fern *Matonia pectinata* collected by Mr. Tansley on Mount Ophir forms the subject of some notes by Miss G. Wigglesworth. The arrangement of concentric steles differs in some respects from the specimen collected in Borneo and described by Mr. Seward. The notice by Mr. V. H. Blackman of a recently published monograph, by Mr. H. Lohmann, on Coccoliths will be useful to those botanists to whom the original memoir is not available. The revised classification of the green Algæ undertaken by Mr. F. F. Blackman and the editor is continued. It was the expressed desire of the editor that the correspondence columns should form a medium for the communication and discussion of educational matters. The attention of teachers may well be directed to the account of a trial of the heuristic method in a secondary school, as well as to a letter which points out the adaptability of systematic botany to meet the requirements of instruction for children.

WE regret that in our last week's issue the name of the fossil Austrian rhinoceros described by Prof. Toula was given as *Rhinoceros sumatrensis* instead of *R. hundsheimensis.*

WE have received a useful paper on American insects injurious to agriculture and horticulture and insecticides, by Mr. C. P. Gillette, forming *Bulletin* No. 71 of the experiment station of the Agricultural College of Colorado.

IN a paper published in the *Memorie* of the Royal Institute of Lombardy (vol. xix. part 7) Dr. A. Negri claims to have discovered in the red blood-corpuscles of mammals a special substance which is abundant during fœtal life and gradually diminishes with advancing age.

THOSE remarkable horned ungulates the titanotheres, of the Oligocene of North America and Eastern Europe, are shown by Prof. Osborn (*Bull. Amer. Mus.*, vol. xvi. art. 81) to be divisible into four branches, or "phyla," characterised by the proportion of the length to the breadth of the skull, and in some cases by the relative length of the limbs. In this respect they resemble the rhinoceroses, the various "phyla," as in the case of the latter, being regarded by the author as representing as many genera.

PROF. OSBORN'S studies of the groups just referred to have led him to take into consideration (*Bull. Amer. Mus.*, vol. xvi. art. 7) the morphological importance of length or shortness in the skulls of mammals—dolichocephalism and brachycephalism—and he concludes that both these features are characteristic of specialised types, the former condition being (as in the horse) often, although not invariably, connected with length of limb and neck, and adaptation to speed, while brachycephalism may be correlated with short limbs and an abbreviated neck. Exceptions to this rule, as exemplified by the cats, are due to special adaptive causes. It may be added that, in a paper published in the *Comptes rendus* of the late Geological Congress at Paris, Prof. Osborn figures a restoration of an American ancestral form of the horse nearly related to the English Eocene Hyracotherium; the animal is represented as fully striped.

IN their recently issued Report the Royal Commissioners strongly urge the necessity for a central authority to have control of the whole of the salmon fisheries of Great Britain, or even of the United Kingdom. As a temporary measure a

controlling authority of sufficient independence might be obtained by a modification of the present departmental arrangements in each of the three countries of the kingdom; but a single department to have charge of all questions connected with salmon-fishing in both seas and rivers is what is really wanted. Whether, however, the control be triple, dual, or single, it is essential that the holder of the office should himself be an expert on matters connected with salmon and salmon-fishing, and that his time should not be frittered away by attention to official details. The second section of the report deals with the life-history of the salmon, which is set forth in considerable detail. The Commissioners point out many deficiencies in our knowledge of this subject, such as whether fish entering rivers at different seasons of the year frequent particular branches or parts of the main river at spawning time. Information is likewise much needed with regard to the migration of kelts, and still more so concerning the history of the fish, both in its immature and adult condition, during its sojourn in the ocean. Experiments have shown that while a certain number of fish return to the rivers they left, others seek fresh spawning-grounds; and it will be obvious that fuller information on this point is of prime importance before steps are taken for the improvement of the fishery in any given district. In regard to the general idea of the deterioration of salmon-fisheries, the Commissioners are extremely cautious, stating that "it is useless to attempt to submit the popular belief that there has been a deterioration to any severe test. We can only accept the fact that such belief exists."

THE parliamentary Blue-book just issued on the working and expenditure of the British Museum for the past year shows that important additions have been made to the natural history collections at South Kensington, and considerable improvements effected in regard to the arrangement of the specimens exhibited to the public at that branch. It is satisfactory to learn that, in cooperation with the Trustees, the Egyptian Government vigorously carried on the survey of the fishes of the Nile during the year, nearly 700 miles of the river having been examined, resulting in the acquisition of several new generic and specific types. In the spring of 1901 Dr. Smith Woodward was dispatched by the Trustees to explore the well-known mammaliferous beds of Pikermi, Attica, with the result that a fine series of remains from this horizon (previously very poorly represented in the collection) was acquired for the Museum. During a visit made to the Fayum district of Egypt in company with Mr. Beadnell, of the Geological Survey of Egypt, Dr. Andrews was fortunate enough to be the joint-discoverer of a hitherto unknown Tertiary vertebrate fauna of remarkable interest. Collections were also made under the auspices of the Trustees in Tripoli. In the Museum itself a section of economic zoology has been established. Among other acquisitions, the collection has been enriched by the magnificent series of birds' eggs bequeathed by the late Mr. Crowley, as well as by the gift of Lord Walsingham's unrivalled cabinet of micro-Lepidoptera and library pertaining to the same. The elephant-seal presented by Mr. Walter Rothschild is likewise a notable addition, which is exhibited in a case (also the gift of the same benefactor) with the Antarctic seals presented by Sir G. Newnes. The series of domesticated animals has been largely increased; and much progress has been made in arranging and mounting the collection of recent mammals and birds according to modern ideas. The insect collection—both in the public galleries and in the study rooms—has likewise claimed a large share of attention on the part of the staff. Indeed, the whole Natural History Branch of the Museum is to be congratulated on a good record of progress.

THREE pamphlets for the information of the islanders have recently been published by the Imperial Department of Agriculture for the West Indies. No. 14, by Mr. Maxwell-Lefroy, deals with "Screw Worm in Cattle at St. Lucia." In October last it was reported to the Department that a "fly maggot" was causing injury to cattle in the island. Mr. Hudson, the agricultural instructor, made careful observations of the habits of the fly and the extent of the injuries it inflicted, and Mr. Maxwell-Lefroy, on the suggestion of the administrator, visited St. Lucia to investigate the matter personally. The fly proved to be the "screw worm" of the southern United States, and also widely distributed in the West Indies. The pamphlet is devoted to the life-history of the worm, its mode of attack, the treatment of the wounds, prevention, &c. No. 15 is entitled "Plain Talk to Small Owners at Montserrat," being the substance of an address to the small cultivators in the island by Mr. Watkins, the Commissioner of Montserrat. In a small compass much information is conveyed in simple language on the value of the soil, manuring, the cultivation of foodstuffs for home consumption and for export, the regulation of the quality of fruit for exportation, bee-keeping and other subjects. No. 16 is by the same authority, "Hints on Onion Cultivation," also an address to the small cultivators of Montserrat. Based on experiments carried on during the past two years on the island, the prospects of the onion industry are considered to be distinctly promising, and this little brochure of twenty-five pages, which gives the essential particulars at every stage, from the selection of soil and seed to harvesting, packing and shipping, should prove invaluable, not only to the onion growers of Montserrat, but also to those of the other islands where the industry is being introduced.

FOR several years past explorations have been carried on by the Geological Survey of Canada in the North-West Territory, chiefly in the Belly River formation of Assiniboia and Alberta. This formation underlies the Fox Hills-Ft. Pierre Group, and is, therefore, Mid-Cretaceous, as distinguished from the Upper Cretaceous Laramie of Wyoming and Colorado, which overlies these marine beds. It thus enables an examination to be made of the characters of the Mid-Cretaceous land fauna of North America. The fossils have been collected by Mr. Lawrence M. Lambe, who has also prepared and figured them. The manuscript report upon this collection, entitled "On Vertebrata of the Mid-Cretaceous of the North-West Territory," has just been completed under the direction of Prof. Osborn. It includes two parts, the first a general introduction entitled "Distinctive Characters of the Mid-Cretaceous Fauna," by Prof. Osborn, the second entitled "New Genera and Species from the Belly River Series, Mid-Cretaceous," by Mr. Lambe. It will be illustrated by twenty-one plates and a large number of text figures, and will appear from the press of the Canadian Geological Survey early in the autumn. The comparison of these Belly River Dinosaurs, especially the Iguanodonts and horned Dinosaurs or Ceratopsia, with those of Montana appears to demonstrate that a part at least of the Montana fauna is contemporaneous with the Belly River and represents an older horizon than the Laramie of Wyoming described by Marsh. The Belly River contains some of the older Jurassic families, which, so far as known, are wanting in the Laramie. The Montana fauna has hitherto been regarded as contemporaneous with the Wyoming and Colorado Laramie fauna, but there do not appear to be adequate grounds for this opinion in the vertebrates now known.

IN the April number of the *Journal of Physical Chemistry* is a paper by Mr. J. E. Mills in which several interesting applications of the kinetic theory of gases are made. By considering the transition from the liquid to the gaseous state in a particular way, an equation is obtained in which all the quantities are measurable, and it affords an experimental test of the

assumption that the molecular attraction varies inversely as the square of the distance from the molecule and does not vary with the temperature. This assumption is found to be in agreement with the experimental data as tested by the equation. It is further shown in the paper that the molecular attraction differs from the attraction of gravity in being determined primarily by the chemical constitution of the molecule and not by its mass.

IN the July number of the *American Chemical Journal*, Messrs. Morse and Frazer give an account of their experiments on the preparation of cells for the measurement of high osmotic pressures. Osmotic-pressure determinations are well known to be attended with considerable difficulties, and the number of experimenters who have succeeded in carrying out the measurement of even low osmotic pressures is comparatively small. Specially constructed porous cells made of fine materials, very uniformly mixed and hard burned, were employed, and the semipermeable membranes were produced in these by electrolysis. The electrical resistance of the membranes so obtained varied very considerably, the lowest resistance being about 3000 ohms and the highest more than 200,000 ohms. From the observations made by the authors it appears that high-resistance membranes are those which are requisite for successful osmotic-pressure measurements, but no certain method of obtaining such membranes has been discovered. Experiments were carried out with half-normal and normal cane-sugar solutions. For the former the osmotic pressure was found to be about 13·5 atmospheres, and for the latter a lower limit of 31·4 atmospheres was determined. It is extremely interesting to note that this osmotic pressure of more than thirty atmospheres was developed within two hours of commencing the experiment, and that the membrane within the cell had a resistance of more than 200,000 ohms.

ALTHOUGH the electrochemical equivalent of silver has been the subject of several very careful investigations, the results obtained by different experimenters indicate that the quantity of silver deposited by a given quantity of electricity is dependent to a certain small extent on the form of voltameter and on the conditions under which this is employed. Messrs. Richards and Heimrod (*Zeitschrift für physikalische Chemie*, vol. xli. p. 302) have investigated minutely the cause of these differences, and find that the most important disturbing factor in the ordinary silver voltameter is the formation of a complex silver ion at the anode which diffuses towards the kathode, and by its decomposition increases the quantity of silver deposited at the kathode. An improved form of silver voltameter is described in which the anode and kathode are separated by a porous cell which prevents the diffusion of the anode solution to the kathode, and the accuracy of the results obtained by the use of this instrument is demonstrated by several series of experiments. As a result of this investigation it appears that the electrochemical equivalent of silver as determined by Lord Rayleigh's voltameter is at least ·05 per cent. too high, and that the quantity of electricity associated with one gram equivalent must now be taken as 96,580 coulombs.

The additions to the Zoological Society's Gardens during the past week include a Geoffroy's Cat (*Felis geoffroii*) from Paraguay, presented by Dr. Jose Carlos Rodriguez; a Somali Ostrich (*Struthio molydophanes*) from East Africa, presented by Mr. A. Marsden; two Lion Marmosets (*Midas rosalia*) presented by Miss E. M. Unwin; a Sykes's Monkey (*Cercopithecus albigularis*) from East Africa, a Macaque Monkey (*Macacus cynomolgus*), a Roofed Terrapin (*Kachuga tectum*), a Hamilton's Terrapin (*Damonia hamiltoni*), four Bungoma River Turtle (*Emyda granosa*) from India, a Moustache Tamarin (*Midas mystax*) from the Upper Amazons, four Long-necked Chelodines (*Chelodina longicollis*), two Vulpine Phalangers (*Trichosurus vulpecula*) from Australia, nine Tigrine Frogs (*Rana tigrina*) from the East Indies, a Californian Toad (*Bufo boreas*), four Pennsylvanian Mud Terrapins (*Cinosternon pennsylvanicum*) from North America, two Blackish Sternotheres (*Sternothoerus nigricans*) from Madagascar, a Lesueur's Water-Lizard (*Physignathus lesueuri*) from Queensland, two Black-pointed Teguexins (*Tupinambis nigropunctatus*) from South America, deposited; a Hoolock Gibbon (*Hylobates hoolock*) from Assam, purchased; a Crested Porcupine (*Hystrix cristata*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

A NEW REGISTERING ACTINOMETER.—M. G. de Fontenoy, of Paris, communicates to the *Bulletin de la Société Astronomique de France*, of August, a description of a novel registering actinometer which he has made and has found to act consistently.

The record is produced by the sunlight acting on a sensitised roll of paper fastened to an inner cylinder in the usual way, but in order to differentiate the varying intensities of the actinic effect, the light is allowed to act on the sensitised surface through a series of small windows, pierced in an outside cylinder of thin brass, which are equal in area and equidistant, but have different degrees of transparency. The whole instrument is rotated so that the common axis of the cylinders is always at right angles to the path of the sun's rays, and the inside cylinder is rotated by clockwork once in every twenty-four hours.

The paper is divided into equal spaces, representing hours, by a series of lines drawn on its surface perpendicular to the direction of its rotation, and a reproduction of one of the charts resulting from the exposure and working during one day in June plainly shows the traces made by the light which passed through the various windows; the longest trace (*i.e.* the one which is shown for the greatest number of hours) is the one which was formed by the light which passed through the most transparent window, the shortest is the one due to the light which passed through the most opaque window. By joining the ends of these traces one gets a curve, the integration of which gives the total amount of light registered during the twenty-four hours if one has previously determined the actinic constant for each window by submitting the instrument to the action of a standard light.

SOLAR PHENOMENA DURING 1901.—The "Commission Solaire" of the Société Astronomique de France has published the observations of sun spots and faculæ during 1901.

Numerous observers scattered all over the globe make these observations and then submit them to the commission. Observations were made on 357 days during the year 1901, and it is hoped that, with the assistance of several recently enlisted volunteers, a complete record will be obtained for this and future years.

During 1901 twelve separate groups of spots, including 392 individual spots, were observed, the sun presenting a spotted surface on sixty days out of the 357 days of observation.

It is recommended by the secretary, M. F. Bouët, that members should also record the barometric pressure, the temperature, and the state of the surrounding atmosphere at the same time that they record the numbers of solar spots and faculæ.

A DARK SPOT ON JUPITER.—In a letter to the *Observatory* Mr. Theodore Phillips describes the movements of the dark spot which was observed in the neighbourhood of the red spot last year. On June 19 this year it was observed than an enormous area of dark material, extending for 35°, followed the *f* "shoulder" of the red spot, and on June 26 a dark spot was observed close to the *p* "shoulder," or *west*, of the red-spot hollow.

Mr. Phillips asks, "How did it arrive at its present position?" and then discusses the various solutions to the question, finally arriving at the conclusion that the dark material must have been diverted to the south by the red spot, and, after passing that obstruction, have regained its former latitude. As there is still a portion of the dark area to the east of the red spot, it would be advisable for observers to pay special attention thereto, as valuable additions to our knowledge of Jovian phenomena may thereby be secured.

Mr. Phillips also records an apparent acceleration, of late, in the velocity of the red spot.

ROYAL SOCIETY REPORT ON THE WEST INDIAN ERUPTIONS.[1]

THE Soufrière mountain forms the northern extremity of St. Vincent, and its general form at once suggests a comparison with Vesuvius. It is a simple cone without lateral or parasitic craters. The one at its summit is surrounded on the north side by the remains of a gigantic crater ring, which has the same relation to the present crater as Somma has to Vesuvius. On the north-east lip of the main crater there is a smaller one known as the New Crater, as it is believed to have originated in the eruption of 1812. It is only one-third of a mile in diameter. It is doubtful whether the New Crater was active during the late eruption, and there can be no doubt that it was from the principal crater, or "Old Crater," that the materials mostly were emitted. Deep valleys, often with precipitous sides, have been cut in the slopes of the mountain, especially on its southern side, and it is in these—and particularly in the Wallibu, Rozeau and Rabaca Dry River—that the greater part of the ejecta of the recent eruption have collected.

Premonitory Signs of Activity.

The eruption of May, 1902, though sudden in its outburst and disastrous in its effects, was far from unexpected. In the north of St. Vincent there were two settlements of the Aboriginal Caribs, and these had been so startled by the frequent violent earthquakes, that in February of last year they were considering the advisability of deserting the district. But the first signs of actual volcanic activity were on Tuesday, May 6. The inhabitants of the leeward side were fortunate in having a clear view of the crater, and warned by the outbursts of steam they fled to Chateaubelair, and other places along the coast-line to the south, so that few lives were lost in this quarter. But, on the windward side, the summit of the mountain, as is frequently the case, was wrapped in cloud. Here, at the base of the mountain, there is an extensive stretch of flat land, known as the Carib country, on which were situated some of the largest and richest estates in the island, with a dense population, mostly black or coloured. So little alarm was felt here, that even on the morning of Wednesday, May 7, when the leeward side was practically deserted, sugar-making was in progress on several estates, and all the operations of tropical agriculture were being conducted as usual. From Kingstown, telephonic messages were sent to Georgetown, which is not far from the base of the hill, stating that the Soufrière was in eruption, but they appear to have occasioned little anxiety. And when, about mid-day on Wednesday, the danger was too obvious to be overlooked, the Rabaca Dry River, and some of the streams on the windward side, usually dry except after rains, were running boiling hot, and could not be crossed. Many fugitives in this way found their escape cut off. It was here that the loss of life was greatest, which, though many escaped, is estimated to have amounted to 2000, including about a dozen white men—the overseers of the plantations. The exact number will never be known, as many were entombed in the ashes where they fell.

Progress of the Eruption.

About mid-day on May 6 the first signs of the eruption were observed by those dwelling on the south-western side of the mountain. At 2.40 that afternoon there was a considerable explosion, and a large cloud of steam ascended into the air. By 5 o'clock a red glare was visible in the steam cloud on the summit. Activity continued during the evening, and at midnight there was a great outburst, and red flames were noticed on the lip of the crater. Next morning from Chateaubelair a splendid view could be obtained of gigantic mushroom-shaped clouds rising to a great height in the air—estimated at 30,000 feet—and drifting away before the north-east trade wind. As the day advanced the eruption increased in violence; by 10.30 a.m. enormous clouds of vapour were being emitted with loud noises, accompanied by much lightning. It is remarkable that at that time the inhabitants of the windward side were still in doubt about the reality of the eruption, since they mistook the dark cloud covering the mountain for a thunder cloud. The mountain was now in a state of continuous activity, and from Chateaubelair it could be seen that the materials were mostly discharged from the old or principal crater. Vast clouds of steam, showers of dark matter (probably mud), and of stones, could be seen projected from it, partly on the leeward, but mostly on the windward side. At mid-day the slopes of the mountain were still green, and the rich mantle of tropical vegetation had not yet been destroyed. A thin layer of fine ash had fallen over the lower ground, only sufficient to give the leaves a greyish colour. The enormous columns of vapour continued to ascend from the crater, with frequent violent outbursts, projecting showers of stones and mud.

About this time it was noticed that steam was rising from some of the valleys on the south side of the hill, and this increased until at 12.50 the whole mountain was suddenly enveloped in a dense cloud of vapour. Just before this the rivers Wallibu and Rabaca had been seen rushing down in raging floods of boiling water. It is most probable that these phenomena were due to the escape of the crater lake, which was driven over the lower or south lip of the crater between 12 o'clock and 1 o'clock on the Wednesday afternoon, and poured down the valleys to the sea. So far as we know there were no mud lavas, in the ordinary sense, flowing down these valleys, but only a tremendous rush of boiling water, which left no traces which we could recognise when we visited the district.

By 1 o'clock the roaring of the volcano was tremendous. Showers of stones were being projected both to windward and to leeward. The enormous columns of steam continued to ascend from the crater. The lightnings were terrific, and after the large outbursts, which took place every few minutes, volumes of vapour might be seen covering the whole area. Hitherto the eruption had been of a type with which geologists are familiar, and the destruction done was confined to the higher parts of the mountain in the close vicinity of the crater.

But about 2 o'clock—to quote the words of an eye-witness (Mr. T. M. McDonald, of Richmond Vale Estate)—"there was a rumbling and a large black outburst with showers of stones, all to windward, and enormously increased activity over the whole area. A terrific huge reddish and purplish curtain advanced to and over Richmond Estate." This was the strange black cloud which, laden with hot dust, swept with terrific velocity down the mountain-side, burying the country in hot sand, suffocating and burning all living creatures in its path, and devouring the rich vegetation of the hill with one burning blast.

The Hot Gases and Dust.

On the leeward coast few were overtaken by the black cloud, as the inhabitants had fled and taken refuge in the villages south of Chateaubelair. Those who were caught were killed or badly burned. One boat was near Richmond at the time the blast swept down. The occupants describe the heat as fearful. Hot sand rained into the boat, and the sea around was hissing with its heat. The darkness was so complete that a man could not see his hand. They saved their lives by diving into the water; when they returned to the surface the air was suffocating, but they continued to dive again and again, and, when at their last gasp, they found that the air cleared, and they could breathe again. This occupied only a few minutes—probably much less in reality than it appeared to them. One man was too exhausted to continue diving; he clung to the gunwale of the boat, and the tops of his ears were severely scorched.

On the windward side of the island an uninterrupted view of the progress of the eruption could not be obtained, owing to the veil of cloud which obscured the summit. By mid-day on Wednesday even the most sceptical were convinced that the Soufrière was in eruption, and that the noises heard continuously were not due to a thunderstorm. Before mid-day there had been very heavy rain-showers, and it was noticed that the raindrops carried down fine particles of ash. Work ceased on the plantations, and those labourers who still remained endeavoured to escape to Georgetown or shut themselves up in their houses. By 2 o'clock fine ashes, with occasional larger stones, were falling steadily, but, as yet, little damage had been done, and no one had been injured. Then came the climax of the eruption, and those who were in the open air saw a dense black cloud rolling with terrific velocity down the mountain. They took refuge in their houses and in the plantation works, where they crowded together in such numbers that in one small room 87 were killed. The cloud was seen to roll down upon the sea, and was described to us as flashing with lightning, especially when it touched the water. All state that it was intensely hot, smelt strongly of sulphur, and was suffocating. They felt as if something was compressing their throats, and as if there was no

[1] Abridged from a preliminary report by Dr. Tempest Anderson and Dr. J. S. Flett, just published in the *Proceedings* of the Royal Society, vol. lxx. pp. 423–445.

air to breathe. There was no fire in the ordinary sense of the word, only the air was itself intensely hot and was charged with hot dust. The suffocating cloud only lasted a few minutes. Those who survived this ordeal mostly escaped, though many died within a few hours from shock, or from the severity of their injuries. In some cases a few survived, entirely or almost entirely uninjured, in a room in which many others died. Most of those who escaped had shut themselves up in the rum cellars or in substantially built houses, and had firmly closed all doors and windows. By the time the hot blast had reached the coast the sand it contained was no longer incandescent, and though still at a very high temperature it did not set fire to wood or burn the clothes of those exposed to it. The burns on the survivors were chiefly on the outer aspect of the arms and legs, and on the faces, and confined to parts not protected by their clothes.

The Rain of Dust.

Complete darkness now covered the whole north end of St. Vincent—a darkness more intense than any the inhabitants had ever before experienced. The fugitives had to creep along the roads or feel their way along the roadsides. The roaring of the mountain was terrible—a long, drawn-out, continuous sound resembling the roar of a gigantic animal in great pain. Fine ash and sand rained down over the whole country with occasional showers of large stones. Some of these were so hot as to set fire to the trash roofs of huts in the south-end of Georgetown, at a distance of 7 miles from the crater. In Kingstown, 12 miles from the Soufrière, the ash was at first moist, but afterwards dry. It had a strong sulphurous smell, and pattered on the roofs like a heavy shower of tropical rain. Around the volcano the earth shook and trembled continuously, and the motion was described to us as undulating rather than resembling the sharp shock of an earthquake. Only in one or two cases were the walls of houses injured. What was taking place on the summit of the mountain no one can tell, but all who passed that night in the vicinity of the Soufrière agree that there was one black suffocating cloud, and only one. In all probability the eruption had reassumed the ordinary phase, and the showers of ash and stones were produced by violent upward explosions of steam. By half-past 5 o'clock the ash was falling in Barbadoes, 100 miles to the eastward, whither it had been carried by the upper currents of air in a direction opposite to that of the trade winds. In St. Vincent the darkness lessened slightly before nightfall, but the rain of dust and the noises lasted until early in the ensuing morning.

When day broke it was seen that in St. Vincent, and even in Barbadoes, everything was covered with fine grey ash resembling a fall of snow. The dust had penetrated into the interior of the houses, where it lay in a thin film on walls and furniture. In Kingstown there were stones as large as a hen's egg; in Georgetown and Chateaubelair some had fallen as much as 1 foot in diameter. Little damage, however, appears to have been done to growing crops, except in the north-end of the island. In fact, many believe that the sulphurous ash had insecticidal properties, and benefited the vegetation. From Chateaubelair it could be seen that the volcano was still emitting puffs of slaty-coloured steam, and showers of fine dust were falling on the leeward side of the mountain. For several days these discharges of vapours continued, but a new phenomenon now attracted more attention. The ravines which furrow the south side of the mountain were found to be discharging clouds of vapour, and this gave rise to reports of fissures having opened on the flanks of the Soufrière, of subsidiary eruptions arising from these fissures, and of streams of lava flowing down the valleys. As a matter of fact, they were really due to the action of water flowing through the hot sand, which in some places had almost obliterated the old stream courses, as will be explained more fully later on. By May 15 the volcanic activity had apparently subsided, and the mountain remained clear and unclouded. The explosions of steam in the valleys continued and are probably still going on.

The state of quiescence continued until Sunday, May 18. Confidence was being restored, and the inhabitants of those districts near the mountain which had not suffered severely were returning to their homes. On the windward side the work of burying the bodies had been completed and things were resuming their normal course. But about 8 o'clock that evening an ominous sound was heard from the crater. Its nature was at once recognised and struck the black population with terror. The noises were as loud as those of the first eruption, and the lightning was very vivid On the leeward side complete darkness prevailed, and ashes and sand fell freely for some hours. In Georgetown the fall of ashes was quite inconsiderable, not exceeding a thin film on the roofs of the houses. Gradually the noises lessened, the darkness lifted, and the moon appeared again. No lives were lost and practically no damage was done, but exactly what happened on those parts of the mountain nearest the crater it is, in the circumstances, impossible to say. This second eruption was the last which proceeded from the main crater. Clouds of steam were sometimes seen gently rising for some days later, but nothing of the nature of a volcanic outburst has since taken place.

Products of the Eruption.

We arrived at Kingstown on Tuesday, June 10, and proceeded at once to Chateaubelair, where Mr. Jas. E. Richards, of Kingstown, kindly placed a house at our disposal. The geological products of this eruption proved to be of very simple character. The Soufrière and the surrounding country were covered with a layer of ashes mostly in the form of fine dark-coloured sand, but mixed with spongy bombs of various sizes and many ejected blocks composed of fragments of the old rocks of the hill. Lapilli and scoria are there in plenty, as is obvious where the heavy rains have washed away the finer material, but the greater part of the ejecta consists of fine sand which, when dry, is hot and yellowish-grey in colour, but when wet becomes almost black. This sand, as has already been noted by many observers, contains plagioclase felspar, hypersthene, augite, magnetite and fragments of glass, and represents a fairly well-crystallised hypersthene-andesite magma which has been blown to powder by the expansion of occluded steam.

The coarser material is mostly a slaggy andesite with crystals of plagioclase and pyroxene. There is little pumice, though we obtained a few fragments which floated on water and contained but few crystals visible to the naked eye. The larger bombs are often black, highly lustrous and glassy when broken across. Some were seen at Wallibu (4 miles from the crater) 3 feet in diameter. The ejected blocks consist of weathered andesites and andesitic tuffs such as can be seen in the walls of the crater. They are very numerous, and some are more than 5 feet across. In addition to these, fine-grained dark green banded rocks occur, which appear to be baked and indurated sediments, probably the mud from the bottom of the crater lake, or the finer beds intercalated in the older volcanic series. Another type of ejected block which is very common in some parts of the hill is a coarse-grained aggregate of felspar, hornblende (brown under the microscope), and perhaps olivine. It is not vesicular and contains little or no glass, being apparently holocrystalline. These rocks are very friable, and the crystals are loosely aggregated together. They seemed to us to be comparable to the sanidinites of the Eifel and many other modern volcanic districts. They are certainly quite unlike true plutonic diorites, both in their structure and in the character of their minerals.

It may be noted that none of these rocks are characteristic of this eruption, but all can be found among the older materials of the hill. The hardened, baked sediments were well known to the Caribs, who have long used them for the manufacture of their finer stone implements. The felspar-hornblende blocks were found by us among the older rocks, and in some places even as rounded masses enveloped in the old lavas. Some of the fresher bombs in the river beds and the seashore can hardly be distinguished from those which were the product of this eruption, though undoubtedly of much older date.

The conclusion was forced upon our minds that immense quantities of hot sand had rushed down the hill into these valleys in an avalanche which carried with it a terrific blast, and piled the ashes deep in the sheltered ravines, at the same time sweeping everything off the exposed ridges which lay between. The rain of volcanic material, which lasted for hours after the hot blast had passed, then covered the surface of the country with a final sheeting of fine dust and scoriæ.

Effects produced by the Hot Blast.

When we ascended the Soufrière, the evidence of the passage of a hot blast laden with sand was overwhelmingly clear. The various stages of its action, and its varying intensity at different spots, are most easily observed on the windward side, where the country is more flat and open, and there are fewer ravines and

spurs to modify the course of its operations than in the Wallibu Valley.

The track to the summit passes across the Rabaca Dry Valley near the shore, then turns upwards through the sugar-cane fields of Rabaca and Lot 14. These were covered with 3 or 4 feet of sand and scoriæ, the trees all bare, their leaves stripped by the falling cinders; but few branches were broken, and no trees had been uprooted or cast down. The woodwork of the houses was unburnt, though the roofs of some of the verandahs, and of the labourers' huts, had collapsed from the weight of ashes that had fallen on them. Many people were killed on these estates. The survivors described to us how the dark cloud had rolled down from the mountain, and how hot and suffocating the air had been when it enveloped them. But it was evident that the velocity of the blast was not above that of an ordinary gale, and the dust it carried, though hot, was not incandescent.

At Lot 14 it was seen that many trees had their limbs twisted off and broken, and some of the negroes' houses had taken fire (probably mostly from hot falling bombs). The blast was more violent here, but not hot enough to set fire to the woodwork or char the green wood of the standing timber.

On the flat ground above the plantation buildings (at an elevation of about 1000 feet), a further stage of devastation was encountered. The fields were here swept bare, the trees broken down, though not as a rule uprooted, their smaller branches swept away; a deep layer of black sand covered the crops of sugar-cane. The blast was here a violent gale.

A little further up the effects of the blast were remarkable. Enormous trees had been uprooted and cast down. Their leaves and finer branches, of course, had disappeared. In every case the fallen trunks pointed directly away from the crater. Even the great cotton-trees, 10 feet or more in diameter, were broken off or uprooted. The smaller trees had in a few cases been swept away like straws. The larger were merely cast down, and lay side by side, their tops directed down the valley, their roots towards the summit of the mountain. Most were charred, some deeply, but, as the wood was green, only the smaller branches had been consumed. The effect was like that produced by a violent hurricane, only more complete, for many of these trees had withstood the hurricane which ruined St. Vincent in 1898. At the lower limit of this region some curious effects of the hot sand blast could be seen. Where any branches or trunks were still standing, they invariably showed themselves to be burnt and eroded on one side—that next the crater—the wood having been charred and the charred material removed by the action of a hot sand blast. On the side away from the crater, the original bark was still left, unburnt, but dry and peeling off; that is, there had been no erosion on the sheltered or lee side of the stems. The wood was too green to take fire, but the sand had been sufficiently hot to char the surfaces which were exposed to it.

Further up the hill—that is to say, above the 1500-feet level, there was little left of the rich tropical vegetation which had covered it from summit to base. Blackened remains of tree-trunks were to be seen, overturned or broken off near the ground, and buried in dark sand. The highest parts of the mountain are as bare and desolate a scene as could be imagined. The ash is 5 to 12 feet deep, and though full of large blocks and spongy bombs, is mostly so fine that when thoroughly wet it becomes a fine mud, very tenacious and slippery, in which one sinks to the knee. In it there is a good deal of burnt timber, utterly blackened and converted into charcoal. Everything has been mown down, and at the same time the intense heat has consumed all the smaller fragments and charred the larger. There is nothing to show what was the velocity of the blast when it left the crater. After a couple of miles it was that of a hurricane or tornado. The limit between the zone of uprooted trees and that of trees still standing, but broken and much damaged, is surprisingly sharp. At 4 miles from the crater the blast was travelling at 20 to 40 miles an hour, and rapidly slowing down. This agrees with the evidence of an eye-witness who saw it when it reached the sea near Chateaubelair. It came over the water with a wave before it, but it did not overturn the small boats which lay in its course.

Another peculiar feature of this blast is the manner in which its course was modified by irregularities in the configuration of the ground over which it passed. To the north of the crater stands the encircling crater wall, already referred to as the Somma. There can be no doubt that a black cloud descended over this side of the mountain, though here the devastation is comparatively slight, and it is inferred that the high intervening ridge overlooking the crater served as a rampart and helped to protect the country behind it from the effects of the blast. The southern lip of the crater, on the other hand, is the lower, and the avalanche of hot sand seems to have poured over this lip almost like a fluid. Down the deep open valley between the Soufrière and the Morne Garu Mountain it rushed, ever following the steepest descent. It clung to the valley bottoms and coursed along them in a manner which somewhat recalls a raging torrent in a river. The streams in these valleys after descending the first part of the hill turn sharply at a right angle towards the coast, deflected by the opposing mass of the Morne Garu. The hot blast mostly followed these valleys, and in them it piled up enormous deposits of sand, but part of it swept up the shoulders of Morne Garu, and tore up the heavy timber which was growing there. The direction in which the fallen trunks point shows that the blast was split into two parts—one taking the east and one the west side of the mountain, rushing upwards obliquely from below. The mountain protected the country behind, and the line of demarcation between the burnt and the green forest almost corresponds with the dividing ridge. The south side is green; the north side towards the Soufrière is devastated and burnt.

Geological Modifications.

Apart from the changes which have taken place within the crater, and the deposits of ash which have formed in the river valleys, and on the surface of the hill, the only other important geological modification of the country has been the disappearance of a narrow strip of coast along the leeward side of the island. Near the mouth of the Wallibu and from thence northward to Morne Ronde, the sea has encroached on the land for perhaps 200 yards. Below Wallibu plantation there stood a village of labourers' huts on a low flat beach with a bluff behind. Here the sea now washes the foot of a cliff some 30 feet high. This cliff consists of soft tuffs covered with several feet of new hot ashes, and is in an unstable condition, as masses are constantly falling down from its face. In this way a new beach is now forming in front of it. It is agreed by those who knew the district before the eruption that not only has the old beach disappeared, which carried the village and the public road, but that part of the bluff behind has also subsided. We were informed by Mr. T. M. McDonald, who is intimately acquainted with this coast-line, that similar subsidences had also taken place, though on a much smaller scale, at several places further north. There is no evidence elsewhere of any changes of level of land and sea. The tide-marks on the rocks and the landing-stages at the villages enabled us to ascertain that the level of high-water was at any rate within a few inches of what it had been before. It was clear that the alterations in the coast-line were due to local subsidence of the foreshores, and that they had mostly affected loose and ill consolidated deposits, such as beach gravels and the fans of alluvium which had formed at the mouths of the streams. The submarine slopes on the leeward side of St. Vincent are very steep, averaging about 1 in 4. Within half a mile of the shore the depth is often more than 100 fathoms.

It seems most probable that owing to the concussions and earthquakes produced by the explosions, some of the less coherent accumulations on these steep slopes slipped bodily into the deep. On this supposition most of the facts would be explained, but at the same time it is possible that at Wallibu the inner margin of the depressed tract may be a fault line. It has a very straight trend, and it is a curious fact that this shore was formerly known as Hot Waters. This might indicate the existence of a fissure up which hot springs were rising.

Comparison of the Soufrière with Mont Pelée.

When we arrived at Martinique, we had the pleasure of meeting Prof. Lacroix, the head of the French Scientific Commission, which had spent some time in making a preliminary survey of Mont Pelée, and the north-end of the island, and from him we obtained much valuable information regarding the sequence of events and the geological consequences of the eruptions in that quarter. It was our intention to make merely such reconnaissances as would enable us in a general way to ascertain the points of difference and of similarity between the outburst of Mont Pelée and that of the Soufrière, and to see what light the phenomena in Martinique threw on the events which had happened in St. Vincent.

Both volcanoes are of the same type, simple cones with a large vent near the summit and without parasitic craters. They are both deeply scored with ravines, and on their south-west sides there is a broad valley—occupied at Martinique by St. Pierre City, at St. Vincent by the Wallibu. It is in these valleys that the destruction has been most pronounced. In both, the recent eruptions have been characterised by paroxysmal discharges of incandescent ashes, and a complete absence of lava streams.

In St. Vincent, however, the mass of material ejected has been much greater, and a considerably larger area of country has been devastated than in Martinique. That the loss of life was not so large can be accounted for by the absence of a populous city at the foot of the mountain. Had the city of St. Pierre been planted at the mouth of the Wallibu, there can be no doubt it would have been equally completely destroyed.

On Mont Pelée, we understand that a fissure has opened on the south side of the mountain between the summit and St. Pierre, from which the blast was emitted which overwhelmed the city. But on the Soufrière the old orifices have been made use of. The eruption of Pelée began with the flow of mud lavas, but none such were seen in St. Vincent. On the other hand, the hot blast which swept down on the doomed city was essentially similar to that which we have described as having taken place at the Soufrière. Both eruptions produced principally hot sand and dust, with a small proportion of bombs and ejected blocks.

Observations of an Eruption of Mont Pelée.

We were fortunate in having an opportunity to witness one of the more important eruptions of Mont Pelée before we left Martinique, and this enabled us to see how far the actual phenomena corresponded with the ideas we had been led to form from an inspection of the effects of the earlier outbursts. On July 9 we were in a small sloop of 10 tons, the *Minerva*, of Grenada, which we had hired to act as a convenient base for our expeditions on the mountain. The morning was spent in St. Pierre City, and on the sugar-cane plantations on the lower slopes of the mountain on the banks of the Rivière des Pères. The volcano was beautifully clear. Every ravine and furrow, every ridge and crag, on its gaunt naked surface stood out clearly in the sunlight. Thin clouds veiled the summit, but now and then the mist would lift sufficiently to show us the jagged broken cliff which overlooks the cleft. From the triangular fissure which serves as the crater hardly a whiff of steam was seen to rise, and the great heap of hot boulders which lies on the north side of and above this fissure could be perfectly made out. Small land-slides took place in it occasionally, and small jets of steam rose now and again from between the stones.

A little after mid-day large steam clouds began to rise, one every 10 or 20 minutes, with a low rumble. As they rose they expanded, becoming club-shaped and consisting of many globular rolling masses, constantly increasing in number and in size as they ascended in the air. They might be compared to a bunch of grapes, large and small, or to a gigantic cauliflower. When their upward velocity diminished they floated away to leeward, and fine ash rained down in a dense mist as they drifted over the western side of the mountain. They occasioned no anxiety in our minds, as we had found that the mountain was never long without exhibiting these discharges, and they were due merely to an escape of steam carrying with it fine dust. They rose, as a rule, to heights of 5000 or 6000 feet above the sea.

That afternoon as the sun was getting lower in the heavens and the details of ravine and spur showed a contrast of light and shadow which was absent at mid-day, we sailed along from St. Pierre to Précheur, intention obtaining a series of general photographs of the hill. The steam puffs continued, and, about 6 o'clock, as we were standing back across the bay of St. Pierre, they became more numerous, though not much larger in size. We ran down to Carbet, a village $1\frac{1}{2}$ miles south of St. Pierre, where there is a supply of excellent water and good anchorage. About half-past six it was obvious that the activity of the mountain was increasing. The cauliflower clouds were no longer distinct and separate, each following the other after an interval, but arose in such rapid succession that they were blended in a continuous emission. A thick cloud of steam streamed away before the wind so laden with dust that all the leeward side of the hill, and the sea for 6 miles from the shore, was covered with a dense pall of fine falling ash. The sun setting behind this cloud lost all its brightness, and became a pale yellowish-green disc, easily observable with the naked eye. Darkness followed the short twilight of the tropics, but a 4 days' old moon shed sufficient light to enable us to see what was happening on the hill-side.

An Incandescent Avalanche.

Just before darkness closed in, we noticed a cloud which had in it something peculiar, hanging over the lip of the fissure. At first glance it resembled the globular cauliflower masses of steam. It was, however, darker in colour, and did not ascend in the air or float away, but retained its shape, and slowly got larger and larger. After observing it for a short time, we concluded that it was travelling straight down the hill towards us, expanding somewhat as it came, but not rising in the air, only rolling over the surface of the ground. It was so totally distinct in its behaviour from the ascending steam clouds that our attention was riveted on it, and we were not without apprehension as to its character. It seemed to take some time to reach the sea (several minutes at least), and as it rolled over the bay we could see that through it there played innumerable lightnings. We weighed anchor and hoisted the sails, and in a few minutes were slipping southward along the coast with a slight easterly wind and a favourable tide. We had, however, scarcely got under way when it became clear that an eruption was impending. As the darkness deepened, a dull red reflection was seen in the trade-wind cloud which covered the mountain summit. This became brighter and brighter, and soon we saw red-hot stones projected from the crater, bowling down the mountain slopes, and giving off glowing sparks. Suddenly the whole cloud was brightly illuminated, and the sailors cried, "the mountain bursts!" In an incredibly short space of time a red-hot avalanche swept down to the sea. We could not see it start from the crater owing to the intervening veil of cloud, but the lower parts of the mountain were clear, and the glowing cataract poured over them right down to the shores of the bay. It was dull red, with a billowy surface, reminding one of a snow avalanche. In it there were larger stones which stood out as streaks of bright red, tumbling down and emitting showers of sparks. In a few seconds it was over. A loud angry growl had burst from the mountain at the moment when this avalanche was launched from the crater. It is difficult to say how long an interval elapsed between the time when the great glare burst on the summit and the incandescent avalanche reached the sea. Possibly it occupied a couple of minutes: it could hardly have been more. Undoubtedly the velocity was terrific. Had any buildings stood in its path they would have been utterly wiped out, and no living creature could have survived that blast.

The Lightning Discharges.

Hardly had its red light faded when a rounded black cloud began to shape itself against the starlit sky, exactly where the avalanche had been. The pale moonlight shining on it showed us that it was globular, with a bulging surface, covered with rounded protuberant masses, which swelled and multiplied with a terrible energy. It rushed forward over the waters, directly towards us, boiling, and changing its form every instant. In its face there sparkled innumerable lightnings, short, and many of them horizontal. Especially at its base there was a continuous scintillation. The cloud itself was black as night, dense and solid, and the flickering lightnings gave it an indescribably venomous appearance. It moved with great velocity, and as it approached it got larger and larger, but retained its rounded form. It did not spread out laterally, neither did it rise into the air, but swept on over the sea in surging globular masses, coruscating with lightnings. When about a mile from us it was perceptibly slowing down. We then estimated that it was 2 miles broad and about 1 mile high. It began to change its form; fresh protuberances ceased to shoot out or grew but slowly. They were less globular, and the face of the cloud more nearly resembled a black curtain draped in folds. At the same time it became paler and more grey in colour, and for a time the surface shimmered in the moonlight like a piece of silk. The particles of ash were now settling down, and the white steam, freed from entangled dust, was beginning to rise in the air.

The cloud still travelled forward, but now was mostly steam, and rose from the surface of the sea, passing over our heads in a great tongue-shaped mass, which in a few minutes was directly above us. Then stones, some as large as a chestnut, began to

fall on the boat. They were followed by small pellets, which rattled on the deck like a shower of peas. In a minute or two fine grey ash, moist and clinging together in small globules, poured down upon us. After that for some time there was a rain of dry grey ashes. But the cloud had lost most of its solid matter, and as it shot forwards over our heads it left us in a stratum of clear pure air. When the fine ash began to fall there was a smell of sulphurous acid, but not very marked. There was no rain.

The volume of steam discharged must have been enormous, for the tongue-shaped cloud broadening as it passed southwards covered the whole sky except a thin rim on the extreme horizon. Dust fell on Fort de France and the whole south-end of Martinique. The display of lightning was magnificent. It threaded the cloud in every direction in irregular branching lines. At the same time there was a continuous low rumble overhead.

What happened on Mont Pelée after this discharge cannot be definitely ascertained. For some hours afterwards there were brilliant lightnings and loud noises which we took for thunder. That night there was a heavy thunderstorm over the north-end of Martinique, and much of the lightning was atmospheric, but probably the eruption had something to do with it, and the noises may have been in part of volcanic origin.

Characteristics of the Eruptions.

There can be no doubt that the eruption we witnessed was a counterpart of that which destroyed St. Pierre. The mechanism of these discharges is obscure, and many interesting problems are involved. But we are convinced that the glowing avalanche consisted of hot sand and gases—principally steam; and when we passed the hill in R.M.S. *Wear* a few days later, we had, by the kindness of the captain, an excellent opportunity of making a close examination of the shore from the bridge of the steamboat. The south-west side of the hill along the course of the Rivière Seche was covered with a thin coating of freshly fallen fine grey ashes, which appeared to be thickest in the stream valleys. The water of the rivers flowing down this part of the hill was steaming hot. This was undoubtedly the material emitted from the crater on the night of the eruption. There was no lava. We saw no explosions of combustible gases, and nothing like a sheet of flame. We were agreed that the scintillations in the cloud were ordinary lightnings which shot from one part of its mass to another, and partly also struck the sea beneath.

The most peculiar feature of these eruptions is the avalanche of incandescent sand and the great black cloud which accompanies it. The preliminary stages of the eruption, which may occupy a few days or only a few hours, consist of outbursts of steam, fine dust and stones, and the discharge of the crater lakes as torrents of water or of mud. In them there is nothing unusual, but as soon as the throat of the crater is thoroughly cleared, and the climax of the eruption is reached, a mass of incandescent lava rises and wells over the lip of the crater in the form of an avalanche of red-hot dust. It is a lava blown to pieces by the expansion of the gases it contains. It rushes down the slopes of the hill, carrying with it a terrific blast, which mows down everything in its path. The mixture of dust and gas behaves in many ways like a fluid. The exact chemical composition of these gases remains unsettled. They apparently consist principally of steam and sulphurous acid. There are many reasons which make it unlikely that they contain much oxygen, and they do not support respiration.

THE PERSEID METEORIC SHOWER OF 1902.

THE display of Perseid meteors was fairly abundant this year, though somewhat marred, and only partially observed, in consequence of the unsettled weather which prevailed. In the west of England the first half of August proved an exceptionally cloudy period, and comparatively few observations could be secured. In the eastern counties atmospheric conditions appear to have been decidedly more favourable, for while at Bristol only meagre results could be gathered from skies wholly or partially veiled with clouds, observers in metropolitan suburbs reported clear weather and collected a plentiful harvest of meteor flights. At Hampstead Mr. G. M. Knight counted 500 meteors during the first fortnight of August. Between August 1 and 5, 167 were recorded, and on August 10, from 11h. 30m. to 15h. 15m., 239 were seen. The majority of them were Perseids of the usual swift, streak-leaving type, and there were minor showers in Cassiopeia, Andromeda, Cepheus and other regions. Mr. Knight has forwarded the writer some charts containing projections of his recorded paths, and the place of the Perseid radiant appeared to be indicated as under. The ephemeris positions given in the *Monthly Notices*, December, 1901, p. 169, are also added for comparison:—

1902.	Radiant.	No. of meteors.	Ephemeris.
	$^\circ$ $^\circ$		$^\circ$ $^\circ$
August 1–3 ...	$37 + 55$ ..	12 ...	$33.9 + 55.0$
,, 4 5 ...	$40 + 55\frac{1}{2}$ ...	26 ...	$37.0 + 55.6$
,, 10 ...	$44\frac{1}{2} + 57$ ...	43 ...	$44.3 + 56.9$

The agreement is fairly good, though the places observed this year in the early part of August are somewhat east of the predicted centres. A certain allowance has, however, to be made for errors of observation.

At Bristol the writer watched for the Perseids on parts of the nights of August 2, 6, 10, 12 and 14, but clouds prevented anything like a thorough investigation of the progress of the display. The Perseids were fairly numerous, and shot from the radiants given below, but very few meteors were seen on August 6 and 14 owing to the clouds, so that the points of emanation on those nights were merely suspected:—

1902.	Radiant.		Ephemeris.
	$^\circ$ $^\circ$		$^\circ$ $^\circ$
August 6 ...	$39 + 57$	...	$38.9 + 56.0$
10 ...	$45 + 58\frac{1}{2}$	...	$44.3 + 56.9$
12 ...	$47 + 58\frac{1}{2}$	...	$47.1 + 57.3$
14 ...	$50 + 57$	...	$50.0 + 57.7$

The year 1900 not having been a leap-year, the maximum was expected on either August 11 or 12. There was an unusually bright exhibition of these meteors on August 11, 1898. It seems that the maximum intensity was well defined this year, for "a magnificent shower of Perseids" is reported to have been witnessed at Odessa on Tuesday night, August 12. The chief radiating point is said to have been at an altitude of 45° or 50° in the north-east firmament. The latter position corresponds approximately with the normal place of the Perseid centre. But, unfortunately, the report mentions no details as to the number of meteors observed or the duration of the observations, and it is impossible, therefore, to form any exact conclusion as to the character of the display witnessed. It will probably be found, however, when particulars come to hand, that it represented nothing more than a tolerably plentiful return of the stream. There are no other descriptions favouring the inference that a strikingly brilliant shower was witnessed. In and since 1898 the Perseids appear to have been richer than usual, though it is extremely difficult to ascertain the relative strength of the shower from year to year owing to the variable conditions affecting the visibility of the meteors. W. F. DENNING.

THE ZOOLOGICAL SOCIETY'S NEW APE-HOUSE.

THE ordinary plan of keeping monkeys in zoological gardens is to house them in cages which, while closed in winter, can be opened to playing-places in the external air in summer. The objection to this course is that, though it gives the great advantage of fresh air, the monkeys emerging from a heated chamber into a cooler atmosphere are very liable to catch cold and suffer from pulmonary complaints. In the case of some of the hardier Quadrumana (such as the Tcheli monkey of Mantchuria and the Cape baboon), there can be no doubt that such animals will thrive best without artificial warmth of any kind beyond the protection of a dry roof, and may be kept in the open air all the year round. This plan, however, would hardly answer in the case of the anthropoid apes, which live in hot, moist climates and are accustomed all their lives to a high and uniform temperature. In constructing the new ape-house for the special accommodation of these animals, the Zoological Society has adopted the plan, which has been tried with some success on the continent, of separating the animals entirely from the evils of a changeable climate by an air-tight glass screen through which only they can be seen by the public. The

further advantage of this plan is that the apes can receive no germs of disease from the visitors, and can be kept behind the screen in a higher temperature than is maintained in the portion of the building allotted to the spectators.

The new ape-house, for which there was much difficulty in finding a convenient site in the already crowded Gardens in the Regent's Park, is nearly square in shape, being about 70 feet in length and breadth. The principal floor is raised some 5 or 6 feet above the level of the ground, in order to secure the animals from the damp of the stiff clay soil upon which the house is built; and the chambers below the principal floor are devoted to the keeper's apartments and to feeding and heating purposes. On entering the spectators' portion, which occupies the north side of the building, by one of the flights of steps which ascend to the outside platform, the apes will be found occupying four large and roomy chambers on the south side. They are entirely separated from the spectators by the glass screen which runs across the building and corresponds to the windows of a fashionable shop in Regent Street. The spectators are on the outside of the screen and the objects to be inspected on the inside. They are in a good light because the interior is made bright and clear by skylights and by four large windows which occupy the south aspect of the building, while the spectators stand in a darker light. The screen has the further advantage that the animals cannot be improperly fed or unnecessarily stirred up with sticks and umbrellas, as is too often the case in the ordinary monkey-house. The apes themselves can hardly be said to be in cages, but live in large rooms some 16 feet square, which are fitted up with tree-branches, swings, and other contrivances for their amusement and exercise. All round these four rooms runs a narrow passage by which the keepers can gain access to any part of them. The temperature of the rooms for the animals is kept at from 80° to 85° F., while that of the portion of the house devoted to the spectators is usually from 10° to 15° less.

The apes that at present tenant the new ape-house are some seven or eight in number, and consist of chimpanzees, orangs and gibbons, representing all the three usually distinguished genera of the anthropoid apes. Besides these, one of the compartments is occupied by a small individual of the very curious proboscis monkey of Borneo (*Nasalis larvata*), one of the most peculiar forms of Old-World monkeys. This has always been found to be a most delicate animal in captivity, and very few specimens of it have ever reached Europe alive. When adult the proboscis monkey is rather a large animal, measuring, perhaps, some 30 inches in the length of its body, while the tail is nearly as long. It is remarkable for its large and elongated nose, of which, however, there is comparatively little appearance in the present young specimen. The young animal is also much more simple in coloration, being of a nearly uniform pale rufous above and grey below, while the adult is brightly and mostly distinctly coloured with yellow and chestnut. The proboscis monkey is an inhabitant of Borneo, and was made known to European science by Wurmb, the Dutch Governor of Batavia about 1780. Preserved specimens of it were first brought to Europe by Sir Stamford Raffles. Captain Stanley Flower received some living examples of it at the Ghizeh Gardens, Cairo, in 1899 (see *P.Z.S.*, 1899, p. 785), but they did not last long even in the favourable climate of Egypt.

THE HABITS OF THE LARVÆ AND ADULTS OF SIREX AND THALESSA.

We have received from Mr. E. P. Stebbing, of Dehra Dun, India, an account of the habits of the larva of a Himalayan species of sawfly (Sirex) and its parasite, an ichneumon allied to Thalessa, of which the following is an epitome. The adult sawfly deposits its eggs in the wood of dead spruce-trees (*Picea morinda*). When hatched, the grubs bore horizontally into the wood for a short distance and then drive a tunnel vertically upwards or downwards after the manner of the European *S. augur*. The débris, after passing through the body of the grub, is so closely jammed in the tunnel that no holes are visible in the wood when sawn through. The pupa is formed at the end of the tunnel, where it lies naked at an angle to the axis of the stem at a variable distance from the exterior. In place of following the old, tortuous track of the grub—for several reasons a matter of difficulty—the adult insect cuts its way to the exterior by the nearest route, which, unlike that of the European species, is not, as a rule, at right angles to the larval tunnel. The mature insect never seems to have the slightest hesitation in determining the direct route to the outer world. It may be added that the larval state seems to last for several years, as grubs of different ages occur in the same trunk.

With regard to the parasitic ichneumon-fly allied to or identical with Thalessa, Mr. Stebbing is of opinion that it never makes the mistake of attacking wood in which pupæ of the sawfly Sirex are not entombed. As to the statement that the ichneumon-fly frequently dies from its ovipositor becoming inextricably fixed in the wood, he suggests that the insect, after depositing its last egg, dies in the position then assumed, as is certainly the case with many of the bark-boring beetles of the family Scolytidæ. As the ovipositor of the ichneumon does not exceed an inch and a half in length, while the spruce-bark may be fully an inch thick, it is considered that the Thalessa must have some means of fixing the position of the Sirex eggs and of the tunnels of the young grubs in the wood underlying the bark. Without such knowledge it would seem an impossibility for the parasite, the ovipositor of which appears of inadequate length for its task, to reach the larval tunnels. Numbers of dead ichneumons were observed in partially bored galleries, this being apparently due to the circumstance that the Sirex larvæ often travel with their parasites to such a depth in the trunk that the adults of the latter are unable to cut their way out. The numbers of the ichneumon are thus, involuntarily, kept down by the sawfly larvæ.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Mr. J. Graham Kerr, of Christ's College, Cambridge, has been appointed professor of natural history in the University of Glasgow, in succession to Prof. John Young, who has resigned.

The Martell scholarship in naval architecture, offered for competition for the first time this year, has been awarded by the council of the Institution of Naval Architects to Mr. L. Woollard, of the Thames Ironworks, Blackwall. The scholarship is of the annual value of 50*l.* and is tenable for three years.

An exhibit to illustrate the state of education in the British Empire will be sent by the Government to the Universal Exposition to be held in St. Louis in 1904. The official exhibits will be limited to education and the fine arts, but facilities will be afforded to trade and individual exhibitors to show products representing British industries.

The last annual report of the Technical Instruction Committee recently presented to the Oxfordshire County Council supplies further evidence of the serious deficiency in the supply of secondary education in many parts of the country, which it is hoped the passing of the Education Bill, now before Parliament, will do much to remedy. The Committee again directs attention to the lack of secondary schools for girls throughout Oxfordshire, and for boys in the district between Chipping Norton and Bicester. In other directions favourable conditions mark the educational activity of the Committee; there has been a general improvement in the agricultural instruction in the rural centres, and good work has been done in supplementing the training of elementary school teachers.

In accordance with the action of the Board of Trustees and the provisions of the will of the late Jonas G. Clark, the founder, the collegiate department of the Clark University, Worcester, Massachusetts, will be opened on October 1. There is to be no charge for tuition for the year ending 1903; for the next year the charge is to be twenty-five, and for the third year fifty dollars. After the third year, the charge per student in all classes will be at a rate to be fixed by the Board of Trustees. The preliminary announcement issued by the president of the college, Dr. Carroll D. Wright, shows, amongst other provisions, that mathematics will be taught as the groundwork of the college education and that sports will be permitted solely "for the development of physical and moral conditions." Special attention is in the future to be given to the "new" psychology, to economics and to sociology.

The Volta Bureau of Washington, U.S.A., for the increase and diffusion of knowledge relating to the deaf, has issued its second international report of schools for the deaf. The data brought together from all parts of the world give a gratifying assurance that a marked improvement has taken place since

1895, the date of the last report issued by the Bureau, in the provisions made in all countries for the education of this unfortunate class. Not only are the charitably disposed of European and American countries fully alive to the possibilities of assisting the deaf by suitable methods of instruction, but, as the report shows, there are schools in good working order in China, Japan, Algiers and other places not often associated with educational progress. It is interesting, too, to learn that upwards of thirty periodicals for the deaf are issued in Europe, and nearly sixty in America.

THE following list of successful candidates for Royal Exhibitions, National Scholarships and Free Studentships (science) has been issued by the Board of Education, South Kensington:—Royal Exhibitions: Charles Cook, Landport, Portsmouth; Gilmour E.-Brown, Balloch, Dumbartonshire, N.B.; Charles J. Stewart, Fratton, Portsmouth; George H. Childs, Portsmouth; William Welch, Fratton, Portsmouth; Edward L. Macklin, Buckland, Portsmouth; Alfred Jones, Crewe. National Scholarships for Mechanics: Herbert G. Tisdall, Beeding, Sussex; Joseph J. Holloway, Saltley, Birmingham; George H. Andrews, Sheerness; John Alexander, Glasgow; Christopher J. Lees, Oldham; Robert Royds, Oldham. Free Studentships for Mechanics: William E. Gardner, Edgbaston, Birmingham; Harold Fowler, Urmston, Manchester; Leonard E. B. Pearse, London. National Scholarships for Physics: Ambrose E. Woodall, Swinton, Lancs.; James H. Brinkworth, Chippenham; Herbert Moss, Leeds; Thomas F. Connolly, St. Albans; A. Henderson McKenzie, Salford, Manchester, Free Studentships for Physics: Evan J. Evans, Llanelly; Wilfrid M. Hooton, Sutton Bridge, Lincs. National Scholarships for Chemistry: Alfred F. Joseph, London; Alexander McDonald, Middlesbrough; Donald F. Blyther, London; James M. Hird, South Woodford, Essex; Howard H. Morgan, Rhayader, Wales; John W. Birkby, Leeds. Free Studentship for Chemistry: Robert G. Kirkby, Whitstable. National Scholarships for Biology: William F. Collins, London; Thomas Southwell, Todmorden; Arthur E. Pratt, London. National Scholarships for Geology: George Haworth, Burnley; Thomas Dewhurst, Burnley.

SCIENTIFIC SERIAL.

American Journal of Science, August.—The terraces of the Westfield River, Mass., by W. M. Davis. Miller's theory of defending ledges gives a better explanation of these terraces than any other, the normal action of a meandering and swinging river sufficing to account for nearly all the details of terrace form.—Notes on the Cretaceous turtles, Toxochelys and Archelon, with a classification of the marine Testudinata, by G. R. Wieland.—The magnetic effect of electric displacement, by J. B. Whitehead, jun. After a short historical account and criticism of the previous work done in this field, new experiments are described, the net result of which is against the presence of the magnetic effect of electric displacement in an amount given by Maxwell's expression. Only once was a positive result obtained, and this is regarded as being liable to question.—Certain relations of plant growth to ionisation of the soil, by A. B. Plowman. The experiments described show that negative charges stimulate and positive charges paralyse the embryonic protoplasm of plants.—The demagnetising effects of electromagnetically compensated alternating currents, by Z. E. Crook. An experimental study of the effects of the alternating current on the magnetic properties of iron and steel, with special reference to the effect due to the current independently of that produced by the circular magnetism.—Nepheline and other syenites near Port Coldwell, Ontario, by A. P. Coleman.—The double ammonium phosphates in analysis, by M. Austin. A study of the best conditions for the determination of zinc and manganese as double ammonium phosphates.—On the electrical resistance of glass, quartz, mica, ebonite and gutta-percha, by O. N. Rood.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 11.—M. Bouquet de la Grye in the chair.—Reflection and refraction by a body undergoing a rapid translation, by M. J. Boussinesq.—On the law of pressures in cannon, by M. E. Vallier. As the expression originally proposed by the author necessitates complicated interpolations, an empirical formula of a simpler nature is suggested which is sufficiently exact.—On entire functions of finite order, by M. Ernst Lindelöf.—On the mode of formation of kathode and Röntgen rays, by M. Th. Tommasina. The study of the unipolar production of the X-rays by M. Jules Semenov led him to the conclusion that the antikathode gives off rays only if it carries an electric charge, and if connected to the earth it gives off practically no rays. Having regard to the theoretical importance of this fact, the author has submitted it to further experimental study. The following conclusions are stated:—The diffuse reflection of the anode flux alone is sufficient to give rise to kathode rays and to Röntgen rays; the phenomenon takes place even when the antikathode is connected to the earth, and the multiple reflection by the walls of a vacuum tube suffices to produce the partial transformation of the anode flux into both kathode and Röntgen rays.—Phenomena observed at Zi-Ka-Wei, China, during the Martinique eruption, by M. de Moidrey. A magnetic disturbance was observed, as at Paris and at Lyons, at a time corresponding with the explosion of Mont Pelée, together with an earth tremor which lasted about eight hours.—New contributions to the physiology of the leucocytes, by MM. H. Stassano and F. Billon.—Hæmoglobinuria of muscular origin, by MM. Jean Camus and P. Pagniez.—On the existence of a kinase in snake poison, by M. C. Delezenne. Snake poison contains a diastase possessing the same properties as enterokinase, or the microbial kinases. It has not yet been determined whether it is distinct from the poisonous principle of the snake venom.—The toxin of tetanus. Observations of the electrical resistance and of the index of refraction, by MM. Dongier and Lesage.—The distribution of the suprarenal bodies of the Plagiostomes, by M. Ed. Grynfeltt.—Observations on the germinative duration of seeds, by M. Jules Poisson. The seeds of plants growing in moist soils preserve their vitality longer than others provided that they do not leave their moist situation.—The verification of the law of barometric heights, by M. W. de Fonvielle.

CONTENTS.

THURSDAY, AUGUST 28, 1902.

A FIELD NATURALIST'S SCIENCE.

The Primrose and Darwinism. By a Field Naturalist, M.A. Camb. Pp. xiii + 233. (London: Grant Richards, 1902.) Price 6*s.* net.

IT is hard to tell why this book was written. The preface alone is enough to condemn it, for in the preface we have in miniature the chief defects of the book—inaccuracy and want of scientific method.

At the foot of p. vi. the author makes the astonishing statement that Darwin's predecessors are to be

"commended for strictly subordinating theory to natural facts. They thus happily avoided the error into which Darwin, in this instance at least, most assuredly and most conspicuously fell."

On p. vii. the author continues,

"We consider that it was most unfortunate for Natural Science that Darwin relied almost so exclusively on artificial observation, or, in other terms, on experiment, for the investigation and interpretation of natural laws in facts connected with the fertilisation of flowers."

That is to say, the botanists are to be commended for not having attempted to solve the problem of the sexual relation between the two forms of dimorphic flowers in the only possible way in which that question can be attacked.

The preface is followed by a chapter of three pages in which some technical terms are defined, and an incomplete account of dimorphism is given. This, we gather, is intended for the general reader, but it is useless for the purpose; indeed, we fail to see what interest such a reader can find in the book. If he is convinced by the Field Naturalist, and consequently gives up his belief in Darwin's work on the fertilisation of flowers, what does he gain? He has lost a coherent and interesting doctrine which, whatever may be its faults, is undoubtedly in agreement with an enormous range of authentic observation and experiment, and one that has stood the test of time, having been before the world in its modern shape since 1862. The reader is told by the Field Naturalist that *Arum maculatum* is a "purely self-fertilised flower"; if his faith endures up to this part of the book, and if he accordingly swallows the statement, he must for the future give up all attempt to find a function for floral structures, the whole build and habit of reproductive mechanism having become meaningless. It is the same throughout the book; we have pages of weak argument directed against well-authenticated conclusions—arguments which, if accepted, would leave floral structures unexplained and inexplicable. And when the author ventures on suggesting a function, we are liable to come across such a theory as that the orifice in the carina of Lotus (through which pollen is obviously and visibly pumped out) is to serve for the ventilation of the pollen stored within the carina!

If the general reader desires to read this book, let him prepare himself by reading a discussion on floral biology by some candid and competent person. And if, after he has seen how the subject can be treated by a rational writer, he still insists on reading "The Primrose and Darwinism," we must leav him to his fate, though we shall continue to be sorry for him.

We do not propose to go through the whole book, but to discuss one or two points and to leave our readers to judge of the remainder; we must indeed confess that we have found it impossible to read the whole.

The author's principal objection to Darwin's experiments is that in order to exclude insects he made use of a covering of netting. This treatment the author assumes, without any evidence, to be injurious to the pollen. He gives (p. 8) his general reasons for believing in this astonishing conclusion.

(1) "The influence of the solar rays would be greatly diminished," and "would be much debarred from exercising their full maturing power on the anthers, . . ."

This may or may not be the case; but what botanist would make such a statement, unsupported by a single experiment?

(2) "Radiation would likewise be almost entirely prevented by the net, and the dew would consequently fail to fall on the anthers. . . . In the mornings of early spring, ... we have frequently found the flowers of the primrose bedrenched with dew."

The general reader would naturally assume that pollen is known to be improved in quality by being wetted. No botanist would have been likely to frame such a hypothesis, for it is well known that pollen is injured by water. And when a Field Naturalist theorises in this way, without giving a shred of experimental evidence, he must be plainly told that he gives up all claims to be considered a man of science.

(3) "In calm weather" the net would prevent "the free access of the wind, and would prevent it from shaking, and so from freely disturbing and distributing the pollen."

Here again not a particle of evidence is given for his point of view.

In Chapter iv. the author gives instances intended to prove the injurious effect of the net. They are quoted from Darwin's "Cross and Self-Fertilisation." One is the case of *Salvia tenori*, which when protected by a net was quite sterile except for two or three flowers on the summit of the spikes which touched the net when the wind blew.

The Field Naturalist (p. 11) says:—

"To attribute the capacity for fertilisation" in the unprotected "flowers to the bees is perfectly gratuitous, as the flowers under the net (when bees were excluded), 'when they touched the net and the wind blew,'[1] produced seeds without any cross-fertilisation."

How the Field Naturalist accounts for the flowers which touched the net when the wind blew being in a more natural condition than those which did not touch it we are unable to guess. He does not show that they were more wetted with dew, and gives, in fact, nothing that can be called a reason for his conclusion. Yet he has to account for a striking difference, since those flowers that did not touch the net were quite sterile. How Darwin accounts for the fertility of the flowers is not clear. They may have been visited by bees. Why does not the Field Naturalist go into this point, which would

[1] An incorrect quotation.

T

probably entail a discussion of the several types of floral structure found in the genus Salvia? We also look for a discussion of the question whether or no the fact that the flowers were pressed against the netting could so far disturb the mutual relations of the parts as to bring about self-fertilisation.

The same want of full discussion is felt in his critique on Darwin's observation on the broom (*Sarothamnus scoparius*). Darwin says the flowers were

"extremely sterile when the flowers are neither visited by bees, nor disturbed by being beaten by the wind against the surrounding net."

The Field Naturalist quotes this passage incorrectly, omitting "when the flowers are neither visited by bees"—and these words are of some importance, for they show that the disturbance by the wind was believed to have an effect analogous to that produced by insects. In another passage ("Cross and Self-Fertilisation," edit. ii. p. 164) Darwin states that "if the flowers are not dashed by the wind against any object, the keel never opens." If the flower is not opened the style remains in the keel surrounded, but either not fertilised or imperfectly fertilised by its own pollen. But if the style and stamens are freely exposed, as would be the case in the flowers opened by the wind's action, the flowers may conceivably be "dashed against" each other and fertilised, even if they cannot be visited by insects. The whole economy of the broom flower should be thoroughly known, and, indeed, fresh observations should be made, before it is possible to draw the conclusion of the Field Naturalist, that the sterilising action of the net accounts for the results.

The same sort of thing is put forward in the case of *Reseda lutea*. Here Darwin says,

"The bees were able to suck the flowers through the meshes, and brought pollen to them from the neighbouring plants."

The Field Naturalist says (p. 13),

"The bees could not possibly reach with their proboscis the side or inside flowers, yet 'the branches were loaded with capsules.'"

As the Field Naturalist was not present when the bees brought pollen to the mignonettes, and as one of the best observers in the world was present, we need not waste more time over this case.

In "Cross and Self-Fertilisation," from which the Field Naturalist takes his cases, he might have found, if he had looked for them, facts which he will find difficult to fit to his theory of the "denaturalising" effect of the net. Darwin gives ("Cross and Self-Fertilisation," edit. ii. p. 357-369) two lists:—(1) Containing plants which, when insects are excluded, are quite sterile, or produce, as far as he could judge, less than half the normal number of seeds. (2) Containing those which, when protected from insects, are either quite fertile or yield more than half the normal number of seeds. The Field Naturalist is bound to account for the fact that many plants are extremely fertile under the net, and he must account, too, for the fact that, broadly speaking, there is a difference between the type of flower found in the two classes. Or, to put it more accurately, in the first or sterile lot 65 per cent. of the genera have asymmetrical or otherwise specialised flowers, while in the fertile lot the specialised genera are 43 per cent.

Why, according to the Field Naturalist's view, should the net be less hurtful to the simple unspecialised flowers? According to the rational view of the matter taken by most botanists, it was to be expected that specialised flowers would be more highly sterile, when insects are excluded, than simple unspecialised flowers. But it is useless to argue thus, for if a female diœcious plant were placed under a net, and were found to be sterile, the Field Naturalist would doubtless account for its sterility by the denaturalising influence of the net, not by the fact that pollen could not reach its stigmas.

Chapter xiii., on "The So-called Dichogamous Plants," may be taken as another instance of the Field Naturalist's method of treating a scientific problem. His notions on this subject seem to be taken from Lord Avebury and Dr. Wallace, neither of whom can rank as original authorities on the question, while we look in vain for references to Sprengel, Delpino and Hildebrand. This is only one instance of the author's ignorance of the literature of his subject. It is probably in consequence of want of knowledge that he sets up an incorrect definition of dichogamy against which to direct his arguments. He ought to be aware that dichogamy does not necessarily mean a complete separation in time of the staminal and stigmatic functions. However, allowing this serious flaw in his point of view to pass, let us see how he deals with a strongly dichogamous species, *Arum maculatum*. He tells us that no flower gives clearer evidence of its own self-fertilisation than the Arum. Yet he quotes an observation of Darwin, who saw minute flies emerge from an Arum, dusted with pollen, and subsequently visit a neighbouring plant. Here Darwin found pollen within the spathe, though the stamens had not burst. No one will pretend that this one observation is conclusive, but it points clearly to the view accepted by botanists that flies carry pollen from the older to the younger spathes, thus fertilising the female flowers[1] before the pollen in the spathe is ripe.

The Field Naturalist principally devotes himself to trying to prove that the Arum does not imprison flies with sufficient regularity and in sufficient numbers to be of any use. He writes (p. 80):—

"About the forced imprisonment of small flies, Darwin says, 'this statement has [now] been shown by Hildebrand to be erroneous,' and Darwin proves that it is incorrect, and that the small flies can escape before the hairs above wither, by his own experiment" ("Cross and Self-Fertilisation," edit. ii. p. 420).

It so happens that Hildebrand's statement (according to Darwin) refers to Aristolochia, not to Arum. But even if it had referred to Arum it would only have illustrated another piece of inaccuracy of the Field Naturalist. What was shown by Hildebrand (as quoted by Darwin) to be incorrect was the old statement that flies which enter the flowers *never escape*, whereas the Field Naturalist seems to consider it an argument against imprisonment occurring at all. His own observations are on a level with this loose treatment of the problem, for he does not say in which of Delpino's stages were the

[1] Often described as ovaries.

Arums in which he failed to find imprisoned flies. He is clearly ignorant of Knuth's and Müller's positive statements as to the presence of imprisoned insects, and of Müller's description of the flies flying vainly against the imprisoning hairs. He describes the stigmas as covered with pollen after the anthers of the same spadix have burst—which is by no means surprising since the stigmas secrete nectar after they have ceased to function.

He throws in the gratuitous guess that the dead flies sometimes found at the bottom of the prison are killed by feeding "on the intensely acrid juice which, as is well known, is secreted by the tissues of the flower." As a matter of fact, precisely the opposite is known, namely, that "juice" of the plant is not acrid, the irritating effect of the tissues as a whole being due to minute pointed crystals. He concludes that Arum is "a purely self-fertilised flower." To one with any knowledge of the subject this statement, appended as a justifiable conclusion from such an array of arguments, is enough by itself to condemn the author.

Chapter xxiii., p. 190, is headed "Trimorphic Flowers. The cleistogamic flowers directly disprove the theory."[1] The hasty reader might suppose that the theory in question is the Field Naturalist's own hypothesis that nets are a cause of sterility. For if sterility can be produced by keeping the pollen from sun, rain, wind, &c., as the Field Naturalist states to be the case, then surely a cleistogamic flower, in which the andrœcium is shut up within the corolla (a covering much more impervious than a net), must be completely sterile, more especially as the reproductive parts are more or less in the dark, a condition known to produce sterility in chasmogamic flowers. This does not occur to our author, who calls the cleistogamic flower Nature's "own natural net."

The Field Naturalist completely misunderstands Darwin's point of view about cleistogamy, which, by the way, is also the view of biologists generally. Cleistogamy is an economical arrangement for securing fertilisation at any price; it is important that cross-fertilisation shall take place, but it is still more important that seedlings of any parentage should be produced. Floral structures are compromises between the two extreme forms, cleistogamy and diœciousness, in one of which offspring is assured, in the other the offspring, *if any*, is cross-fertilised. The existence of cleistogamy, instead of being fatal to "the theory," is a most instructive part of the body of facts on which the modern view is founded. Why the Field Naturalist supposes that "cleistogamic flowers directly disprove the theory," especially in the case of trimorphic plants, is not obvious, for the meaning of cleistogamy is the same in any class of flowers. We fail to see that his discussion throws any light on the subject. The only point which is worthy of notice is a quotation (p. 191) from Darwin's "Forms of Flowers," which has several copyist's mistakes, and, moreover, contains interpolated words which do not occur in the original, the whole being within inverted commas. It is this sort of treatment of Darwin's text that makes it almost impossible to read the Field Naturalist. We can never know whether the quotations are correctly given, and life is not long enough for the verification of his innumerable citations. There is, however, little in the book but quotations and criticism, and when the reader distrusts the quotations and can see no value in the criticisms, the task of getting through the book becomes unbearable.

We would urge the author to give up his barren attempt to discredit work of such perennial value as Darwin's by niggling bookish methods. Let him rather imitate Darwin's life-long habit of absolutely honest experiment, coupled with broad-minded discussions in which all facts and considerations which oppose his views are brought into full prominence. Then, and not until then, can we take his writings seriously.

[1] We have omitted the letter "D" which forms part of the title, and shows that the chapter continues the previous section C.

CHRONOMETRY.

Exposition universelle de 1900. *Congrès international de Chronométrie. Comptes rendus des Travaux, Procès-verbaux, Rapports et Mémoires.* Pp. xl + 254. (Paris: Gauthier-Villars, 1902.)

AMONGST the numerous congresses at Paris in 1900 was one on chronometry, of which the work under review is the official publication. In addition to the "minutes" of the meetings, which include abstracts of the communications, it gives the full text of more than thirty papers and reports. These deal with such subjects as the testing of watches and chronometers, the decimalisation of time, questions of units and standards, topics of historical or current interest in horology, the description of novel instruments or materials, and mathematical and physical investigations bearing on chronometry.

M. de Vanssay, one of the secretaries to the Congress, gives an account, pp. 5–12, of the tests applied to watches and chronometers at the chief testing observatories. On pp. 153–156 is the report of a commission appointed to consider the question of watch tests, with a view to securing uniformity at different places. The commission confined its attention to the regulations in vogue at Geneva, Kew and Besançon, which are similar in general character, and to new regulations proposed for Neuchatel. While generally favourable to the Geneva-Kew-Besançon rules, the majority of the commission preferred the Neuchatel method of dealing with the results obtained at different temperatures. The commission recommends the addition of a two days' test with the watch vertical pendant *down*, excessive difference between the rate in this position and in the other vertical position pendant up to be a cause for rejection. It makes other recommendations tending to increase the severity of the tests. It recommends that the marks obtained by a watch be given only in the official list of the testing institution, and expresses a wish that all observatories should assign marks according to some common scheme.

A second subject considerably discussed was the decimalisation of time, papers on this topic occupying pp. 116–145. M. Guyou would accept the existing hour and subdivide it decimally; but he would do so only in the case of clocks or chronometers, "tropomètres," used for astronomical or nautical work, whilst the general public would be left to the existing clock or "garde-temps." M. de Rey-Pailhade is more advanced, though his argument that the metre is "admirablement proportionée à la taille de l'homme" rather savours of

antiquity. He proposes a unit the "cé" or 1/100th of the day, subdividing it into the "décicé" and "millicé." In the meantime, he would confine the system to men of science, but would teach it in the schools as soon as it meets with international approval. M. Goedseels considers the greatest obstacle to progress to be the existence of numerous tables and costly instruments based on the sexagesimal system. To help to remove this obstacle, he contributes seven pages of tables for converting time and angles to a decimal system. He takes the hour and the degree as units for one system; for a second he supposes the day divided into forty hours, the circumference into 400 grades. Dr. F. Jaja advocates a system similar to that of M. de Rey-Pailhade; but instead of "cé" he calls his unit "degré," its multiples "décagrade," "hectograde," its submultiples "décigrade," &c., down to "décimilligrade." For use by the public, he suggests for the subdivisions the titles "minute première," "minute seconde," "moment" and "instant."

The English equivalent of a "minute seconde" would be found rather awkward, and why should an "instant" be shorter than a "moment"? In England decimalisation of time may appear rather a remote topic, but it seems to have met with considerable favour at the Congress. The fact that a standing committee was appointed on the subject may not mean rapid progress, but M. Guyou mentions that his system has had a nine months' trial on five French cruisers.

Units form the subject of short papers by M. Lippmann, pp. 175–6, and Dr. Guillaume, pp. 179–183, and of a report by a special commission, pp. 184–6. M. Lippmann's paper is theoretical, treating of various alternatives to the present second as unit of time. One is based on the Newtonian constant of gravity, a second is a submultiple of the sidereal year, a third is the time of vibration of a simple pendulum the length of which (at a given place presumably) would subtend a certain angle at the earth's centre, a fourth is based on the oscillation period of a condenser. Dr. Guillaume's paper is practical. He suggests the classification of watch movements according to diameter. Taking 2 cm. as point of departure, he suggests that the interval between successive classes should be 2 mm. above this point and 1 mm. below. For balances he takes the formula $T=\pi\sqrt{I/M}$ for a French (or half) vibration, where I is the moment of inertia, and M is the "moment elastique" (stiffness) of the spiral spring. He suggests that the number of the *balance* be the value of $\pi\sqrt{I}$ and the number of the *spring* be $\sqrt{M}$, both expressed in C.G.S. measure. These suggestions meet with considerable favour in the report of the special commission. The institution of definite types, with the elimination of intermediate sizes, is, of course, an important one for watchmakers.

Amongst the papers bearing on topics of historical or current horological interest may be mentioned those by Rodanet on the proper definition of a chronometer, by Ditisheim on the classification of escapements, by Kaiser on the price and scientific value of chronometers, and by Caspari on the chronometers of the French navy. In the paper by Ditisheim, pp. 40–46, there are a number of interesting data bearing on the comparative merits of different escapements. We have also a paper by A. Cornu, pp. 55–59, on the phenomena observed in magnetised watches, with a full discussion of the effect of changing the position of a magnetised watch relative to the earth's field; while Brillouin, pp. 164–174, treats experimentally of rapid variations in the amplitude of oscillation of balances, with special reference to the question of the shape and finish of the teeth of wheels.

Amongst the papers dealing with instruments may be mentioned those by A. Cornu, pp. 47–54, on the clock at Nice, by Maillard Salin, pp. 63–5, on "montres-a-billes," by Féry, pp. 69–72, and Thury, pp. 146–152, on applications of electricity, by Borrel, pp. 204–7, on a kind of Venetian blind semaphore for signalling time to ships, and by C. W. Schmidt, pp. 113–5, on his chronograph. This last instrument appears to be employed in France for measuring the velocity of projectiles, and is said to give velocities up to 700 metres a second correct to about 1 part in 500 A specially important paper is that by Dr. Guillaume, pp. 90–112, on nickel steels and their applications to horology. The substance of this paper has mainly been published elsewhere, but it is presented here in a convenient form and it attracted considerable attention at the Congress. Dr. Guillaume has yet another interesting communication, pp. 195–7, on an instrument for drawing the terminal curves of spiral springs in accordance with the results of Phillips's well-known application of the mathematical theory of elasticity.

The mathematical papers, though mentioned last, are by no means least in evidence. M. Faddegon, pp. 13–33, treats of the effects of changes of temperature on ordinary and on compensated pendulums. The formulæ he arrives at for the "grid-iron" pendulum are complicated and those for the mercury pendulum still more so. In the latter case we encounter on p. 27 a determinant with ten rows and columns, and the mere look of the formulæ on pp. 32 and 33 will probably suffice to damp the ardour of anyone anxious to combat the author's conclusion, on p. 31, that it would be well for scientific purposes to give up attempts at compensation and revert to homogeneous pendulums.

M. Goedseels, pp. 73–89, treats of mathematical processes, less exhausting than least squares, for determining constants in linear formulæ containing a considerable number of terms. Comparing the methods of Cauchy and of Tobie Mayer, he concludes that in point of simplicity the advantage rests sometimes with the one, sometimes with the other, according to the circumstances of the problem. But in the case of the ordinary 6-term formula for the rate of chronometers he decides in favour of Mayer.

The final mathematical memoir, pp. 217–252, consists apparently of a collection of already published papers by M. E. Caspari, the acting president, which the Congress decided to reprint. The common subject is the isochronism of helical springs. Calculations are made, after the methods of Phillips, Resal and Yvon Villarceau, of the influence of the "centrifugal force" acting on the balance through its own motion, of the inertia of the spring, and of air resistance, friction, &c. There is also an investigation into the possibility of obtaining isochronism by varying

the length of the spring without having its terminal portion shaped after one of Phillips's curves. On p. 240 it is concluded that, provided the windings are numerous enough, there are in each turn two points diametrically opposite, the attachment of which to the balance would procure isochronism. The paper contains also references to some experiments, and certain mathematical functions are tabulated. The memoir is one which only an expert elastician can follow, while an unprejudiced technical expert could alone judge of its practical value. This implies a combination doubtfully existent in England.

The book as a whole is full of ideas, and contains in addition many valuable facts. It is well worth the attention of horologists, whether practical or theoretical. In some of the papers, however, there are indications of a little haste, or of careless proof-reading. M. de Vanssay's description of the Kew watch trials seems to be founded on a set of regulations superseded in 1890. He specifies different rejection limits as applying to ordinary class A watches and to those obtaining the distinction "especially good." This is not now the case, the distinction denoting simply the attainment of at least 80 per cent. of the total possible marks. In some of M. Faddegon's mathematical expressions there are a few rather obvious misprints, and the paging is wrong in the few cross-references in the text of his paper.

In M. Féry's description of a pendulum with electric "restitution" the letters employed in the text are omitted in Figs. 1 and 2 on p. 70, rendering the description difficult to follow. There are a good many slight errata in intermediate steps in M. Caspari's memoir. Thus on p. 234 the sign of equation (7) is wrong, and the term containing b in the line above is also given incorrectly. The suffix in a_1 is omitted somewhat arbitrarily on pp. 239 and 244, and on the latter page its factor $\sin\phi$ is omitted several times. The errata, however, are seldom of a kind likely to cause serious trouble.

C. C.

TRADES' WASTE AND RIVER POLLUTION.

Trades' Waste: its Treatment and Utilisation. By W. Naylor. (London: Charles Griffin and Co., Ltd., 1902.)

IN this volume the author, who is the chief inspector of rivers of the Ribble Joint Committee and consulting engineer on sanitation and rivers' pollution to the Somerset County Council and other public bodies, has put together the results of his experience and observation, as to the causes of the pollution of rivers and as to the best known practical means of preventing it. The subject, it need hardly be said, is of the greatest importance, but it is also one of ever-increasing difficulty and perplexity. It has been forced upon public attention with more or less insistence at irregular intervals during the last half century. In 1867 the whole question was relegated to a Royal Commission, the reports of which are justly styled by the author as by far the best production on the subject hitherto published in any country. The labours of this Commission paved the way for the Rivers' Pollution Act of 1876, but this, as administered by the various local sanitary authorities, proved to be of little practical good. There can be no question that if it had been efficiently administered much might have been accomplished, and by simple means, and we should not have had to wait for the more costly operations which have resulted from the Local Government Act of 1888. Had the local authorities put the Act in operation with the vigour which they showed in the case of the Alkali Works Regulation Act a great public benefit might have been effected with comparatively little friction or irksomeness. The author points out how the opportunity was allowed to slip.

"Land on which to instal plant might have been obtained which cannot now be procured, and machinery might have been put down, and drains laid at levels which would have permitted the interception of the drainage without the resort to pumping now in many cases necessary. But this was not done. Manufacturers are just as much to blame themselves as anybody. In many cases it was due to their opposition as large ratepayers or to their personal influence on the local governing authorities, that the Act remained a dead-letter."

Whether the larger powers vested in such bodies as the two boards of the Mersey and Irwell Joint Committee and the Ribble Joint Committee, some of which have also been acquired, or sought to be acquired, by county councils, will result in a larger measure of good remains to be seen. But it is evident from the manner in which various trade associations, as, for example, the Paper Makers' Association, have been moved that a more stringent administration of the Act throughout the country is in contemplation, and that the opposition, overt or covert, of many of the manufacturers has still to be reckoned with.

In a chapter on chemical engineering the author deals with the general principles underlying the treatment of trades' waste, either as liquid or semi-solid products. He discusses the "laws" regulating the subsidence of solid particles floating in liquids, the conditions determining their aggregation and the various modes in which precipitants are manufactured. He then gives typical illustrations of the application of these principles as carried out in actual practice, as in the Mather and Platt system and in the continental tank systems. He gives details of the mode of construction of precipitation tanks, together with a design of retaining walls for resisting hydraulic pressures, &c. This chapter is illustrated by diagrams and plans, together with a number of well-executed "process" reproductions of photographs of installations in actual use. It is not, however, very obvious why it should be headed "Chemical Engineering," since it is mainly concerned with the application of physical and mechanical principles to the filtration and clarification of more or less turbid liquids.

The remaining chapters, seven in number, deal with some of the special industries which produce waste in notable amounts, such as woollen mills, tanneries and fellmongeries, breweries and distilleries, bleach and dye works, calico printing works, paper making and chemical works. As a matter of fact, however, the author treats only comparatively few of the waste-producing industries.

The various industries, adopting the classification of the Society of Chemical Industry, may be grouped into twenty-two classes. According to the author, only five of these may be said to have no liquid waste of consequence as regards volume, whereas the remaining

seventeen have both liquid and solid waste, and in the greater number of these the liquid waste preponderates.

But those industries selected by the author for special treatment are undoubtedly among the greatest sinners as regards possible river pollution. Their waste is, as a rule, particularly difficult to deal with, and a study of the means adopted in the several instances presents many features of interest to the sanitary and municipal engineer.

The work has been judiciously put together, and the examples of plant selected for special description are in all cases typical examples of their class. It is admirably printed and illustrated, and the diagrams and drawings are such as will commend themselves to the practical man. The work is specially addressed to borough engineers and surveyors, and we trust that it will be as widely read and studied by them as it deserves to be.

OUR BOOK SHELF.

Die Weltherrin und ihr Schatten. Ein Vortrag über Energie und Entropie. Von Dr. Felix Auerbach, Prof. a. d. Universität Jena. Pp. 56. (Jena: Gustav Fischer, 1902.) Price Mk. 1.20.

DR. AUERBACH no doubt undertook a very difficult task when he endeavoured to popularise the exact significance underlying the expressions "energy" and "entropy," and the relations subsisting between them, and it is not easy to say how far he has succeeded in making himself intelligible to an unscientific audience. Doubtless, of energy everyone believes himself to be more or less well informed, but of entropy, though perhaps not really more difficult of apprehension, yet from its less familiar use very great perplexity and uncertainty seem to exist. We can only hope that the author dissipated some of the clouds which hover around this intricate subject. The somewhat fanciful title of "The Mistress of the World and her Shadow" which is attached to the address leads one to expect a more picturesque and imaginative treatment than the subject receives. One looks naturally for a new set of metaphors and illustrations by which a rather dry subject may be illuminated and its treatment rendered more entertaining, but one does not find much that is new or very appropriate, though of course the matter is sound, and doubtless as a popular address the lecture was very effective.

We are glad to see that it has since been published in *Himmel und Erde*, where it is likely to meet with many and appreciative readers, and thus reach a wider audience than is possible in a lecture theatre. The authoritative version is accompanied by a short list of works connected with the general subject, and also some pages of explanatory notes from the professor addressed to those who are supposed to have some slight previous knowledge of the subject. Notes attached in this way are usually a tacit admission on the part of the author that he has failed to accomplish the task that he has undertaken. We see no reason to view these notes in a different light.

Chemisch-Analytisches Praktikum. Von Dr. Karl Anton Henniger. Pp. viii + 127. (Brunswick: F. Vieweg und Sohn, 1902.) Price Mk. 1.50.

THE chief interest of this book lies in the fact that the author is head-master of the Charlottenburg Real Gymnasium, and that the course which he describes is the one adopted in that institution. We have thus an opportunity of seeing what kind of practical chemistry is cultivated in one of the first-class German schools. According to the author, the goal to be reached by the great majority of his pupils is a knowledge of the chief reactions of the non-metals and metals, as well as sureness and clearness concerning the procedure of analysis and the use of the distinguishing reagents. This is to be effected by exercising in simple analysis.

If this be the case, it may be said that the book is well calculated to fulfil its purpose, for it is substantially a treatise on qualitative analysis prefaced by some useful exercises on different types of chemical action. Descriptions and equations are given for all the tests that are to be performed, and the pupil is, in fact, put through a regular analytical drill. The amount of detail is surprising considering that we are concerned with school-work, and it is difficult to see what would be left for the university to teach in the way of qualitative analysis if the students came with a mastery of this book.

It is remarkable that the course of chemistry here prescribed for school purposes is of the kind that, with pretty general approval, has been steadily disappearing from English schools during the past fifteen years. In this corner of education Germany can hardly be said to show the way.

A. S.

La Protezione degli Animali. By N. Licò. Pp. viii + 64. (Milan: U. Hoepli, 1902.)

THE appearance of this "booklet" may be taken as an indication that the proper treatment by man of the inferior animals and the avoidance of unnecessary and wilful cruelty are attracting attention in countries other than our own. Indeed, Turin, like Paris, possesses its own Society for the Protection of Animals, and the crusade against bearing-reins and other forms of minor torture is carried on as vigorously (and, shall we say, as vainly) as in London.

The author commences with a chapter on the duty of humanity to animals in general, and then proceeds to discuss the various groups of animals brought more especially into contact with man, and the cases where amendment in their treatment is most urgently required. In general, the arguments appear to be put temperately and moderately, even in regard to that thorny subject vivisection. Such sports as dog-racing (under the conditions in which it is conducted in some continental countries), cock-fighting and bull-fights the author unhesitatingly condemns. He is likewise averse to all mutilations of animals, whether to "improve" their appearance or for other reasons. But minor matters, such as the treatment of horses by cavalry soldiers and coachmen, and the nature and fitting of their accoutrements and harness, claim a share of attention. Whether the author will succeed in convincing the world that a vegetarian is preferable to an animal diet may be more than doubtful, but if the book leads to a diminution in any degree of certain forms of cruelty to animals from which this country at any rate is free, its publication will not have been in vain.

R. L.

Coal Cutting by Machinery in the United Kingdom. By Sydney F. Walker. Pp. 144. (London: The *Colliery Guardian* Co., Ltd., 1902.)

THE complaint has frequently been made against mine owners in this country that they are not availing themselves of coal-cutting machinery to anything like the same extent as mine owners in the United States. The complaint is justifiable, inasmuch as any methods by which labour and capital can economise are now absolutely necessary. In his excellent monograph on coal cutting by machinery, Mr. Walker shows that the question is by no means new to this country. The history of the coal cutter in Great Britain is an ancient one. Indeed, the earliest proposal to substitute the labour of a machine for that of a collier appears to have been made by Michael Menzies, of Newcastle-on-Tyne,

towards the end of the eighteenth century. The historical portion of the work shows the evolution of mechanical coal cutting in Great Britain since that date. Descriptions are given of every machine that has been put to practical use, as well as detailed particulars of those that are now in successful operation. The conclusions drawn by the author from his elaborate investigations are that the whole of the coal of Great Britain must be cut by machines, or the industry will find itself in much the same condition as the corn-growing industry, swamped by American production. The pillar and stall method of mining should be replaced by the long wall method, and coal-cutting machines would render blasting unnecessary. The most serious problem to be dealt with is that of cutting coal under a weak roof. The difficulties are perhaps hardly sufficiently emphasised by the author. In a tender coal the roof is crushed down on the machines, or supports have to be set near the faces. These get in the way of a machine. Moreover, machines are so noisy when at work that it is impossible to hear the preliminary warning sounds that the roof generally gives before it breaks down. Eventually, no doubt, it will be ascertained which machine can best be adapted to these conditions, or how the conditions can be modified to suit the machine that promises best.

The author's lucidly written and well illustrated volume cannot fail to prove of great value in directing the attention of mine owners to problems that, at the present time, are of the utmost importance.

Metallography: an Introduction to the Study of the Structure of Metals, chiefly by the Aid of the Microscope. By Arthur H. Hiorns. Pp. xiv + 158; with ninety-six illustrations. (London: Macmillan and Co., Ltd.; New York: The Macmillan Company, 1902.) Price 6*s*.

THE study of the properties and constitution of metals and alloys has made great progress during the last few years, and has reached a point when it can no longer be neglected by engineers. Steel workers have already received some guidance from the labours of metallographists, chiefly, perhaps, from investigations on what Osmond called the "pathology of metals," and the time may not be far distant when the microscope and the pyrometer will form part of the outfit required in the ordinary testing of materials. Metallography has been regularly taught for some time at many of the technical schools both in this country and in America, and it is remarkable that no text-book on the subject existed in the English language before the publication of the work under review. The researches on which Mr. Hiorns has based his book are scattered and highly specialised, and the acquirement of a general elementary knowledge of the subject has been a difficult matter for the student. The appearance of this book is, therefore, particularly well timed, and it will be eagerly read by many, who will not be disappointed by what they find.

The author has carefully collected most of the important results which have recently been obtained, and has given a terse and lucid summary of them which is surprisingly complete, considering the modest dimensions of the book. He has not devoted much effort to the philosophic aspect of the subject, but that is, perhaps, just as well, inasmuch as the science is in its infancy. With regard to the illustrations, exception may be taken to many of the photomicrographs, which appear to have been taken from a set of poor negatives. On the other hand, they have been beautifully reproduced on special paper. In the study of steel, the author has handicapped himself unnecessarily by using such low powers of magnification that some of the structures of which he speaks cannot be seen at all. Nevertheless, taking the book as a whole, Mr. Hiorns deserves the thanks of his fellow workers and teachers for the useful aid he has given them.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Notes on Young Gulls.

IN northern Bohemia there is a large pond or artificial lake—the Hirschberger Grossteich—with a small, rocky island. This is a favourite breeding-place of gulls. Most of these are *Larus ridibundus*, but some *Sterna hirundo* also breed on the rock. For the purpose of studying its plankton I have repeatedly visited this pond, and have thus had occasion also to make some observations on the gulls which may perhaps be of interest to readers of NATURE.

The rock island which forms the breeding-place is some 400 square metres in extent, and rises in ledges to a height of 15 metres. It is composed of the Cretaceous "Quadersandstein" of those parts, partly bare and partly covered with patches of tough, greenish-brown grass and brighter green thistles. The *Larus ridibundus* nests on this rock are pretty carefully built and entirely composed of dry leaves of bulrushes. There are generally three eggs in each nest. At the height of the breeding season there are about 200 such nests on the rock, besides the much less numerous Sterna nests. The nests usually lie on the bare rock close to the margin of a patch of vegetation. The dirty brownish-yellow and black-spotted, mimetic colouring of the down-covering of the young is very effective. When from two to ten days old these young crouch, on being disturbed, against the half-dry grass-tufts and thistles close to their nest, and are then by no means easy to detect. It seems to me that the colouring of these young gulls is not quite the same as that in young of the same species breeding in different environments. It is quite likely that we have here a case of adaptation of the colour of the young to different surroundings, *unaccompanied* by any difference in the colouring of the adult into which they develop. Older ones, which are already beginning to replace the down with feathers, but in which the head is still entirely covered by the primitive yellowish-brown and black down, do not, as a rule, try to hide themselves in this way, but hurl themselves into the water and swim away rapidly when the boat approaches the rock. The old birds scream loudly and try, first, to entice the intruder away in the usual manner by slowly swimming and flying about near the boat and pretending to be wounded and lame. Besides this, however, they also swoop down on the swimming young, sometimes pushing them right under the water. The first of these actions clearly tends to draw the attention of the intruder away from the young; the second has the very opposite effect. Perhaps it may be accounted for in this way. The young have—this can be observed clearly enough—no idea of the nature of the movements of a boat, and often try to escape it by swimming straight ahead in front of the bow. It gives the impression that the old birds try by their screams to convey instructions to the young about the direction in which they should swim so as better to escape the boat. The young, however, often appear not to understand or to heed these "words of advice," whereupon the old birds pounce down on them and give them one or two good slaps with their wings so as to make them understand and obey. These sharp lessons do not seem to be of much good, however. After being thus slapped, the young continue to swim straight ahead of the boat as stupidly as before.

One of the eggs I brought home and hatched artificially. The bird began to chirp in the egg a few days after I had placed it in the oven, upon which I cut away the blunt end of the eggshell and found, as was natural after hearing the bird give voice, the beak protruding into the air-chamber. On the fourth day after this the young gull left the egg-shell. It then weighed 22·7 gr. We weighed it daily for a fortnight. The average daily gain of weight during this time was 8·5 gr.

The daily increments were quite irregular, varying between 1·6 and 3·2 gr. the first four days, and between 5 and 27·5 gr. the latter ten days. These irregularities were, of course, due to differences in the quantity of the contents of the intestine. One day—not three, as has been stated by Prof. Thomson (NATURE, vol. lxiv. p. 588)—after birth the young bird swam about when placed in water just as well as a young duck. For

the first six or seven days it preferred to stand on its *heels*, and usually rose to its toes, that is, the normal position of the adult, only when walking.

The bird often ate indigestible things, little stones, &c., not, as it appeared to me, altogether accidentally, but chiefly and purposely, after it had made a good meal off some living food—Tenebrio larvæ, Limnæus, or the like. Smaller edible things like ants' chrysalids it picked off the ground itself very early, but larger morsels, bits of fish, mice, &c., it only takes when held in the hand and presented to it even now, when it is eight weeks old. The stones, &c., it occasionally eats, and the hair and larger bones it has swallowed it brings up and vomits in a mass. It lost the thorn of the beak on the fourth day and began to fly a little after four weeks; when seven weeks old it began to make longer excursions, and flew—without precept or example—very well. It has, however, not yet attained to anything like the elegant flight of full-grown gulls, and occasionally makes an involuntary somersault in the air when trying to soar or rest on the wind without flapping its wings. R. V. LENDENFELD.

Prague.

The Effect of Light on Cyanin.

WHILE working on the reflective power of cyanin mirrors I have noticed some very interesting effects of light on that substance. Freshly fused cyanin is of a deep metallic bronze colour, but exposure to light turns it plum colour and finally a steely blue-black. In the moderate light of a cloudy day the change is perceptible in half an hour, in direct sunlight in less than a minute. The complete change to blue-black requires an exposure of about twenty hours to diffuse daylight or half an hour to direct sunlight. It has long been known that cyanin is unsuitable for use as a cloth dye on account of its rapid fading in sunlight, but recent investigators of the optical properties of this substance appear to have overlooked this light effect. That the effect is purely photographic and not due to any rise in temperature is shown by the fact that long-continued heating in the dark produces no trace of discoloration. On the contrary, the effect of heating is to reverse the effect produced by the light, for a thin coating of cyanin, exposed until blue-black throughout, returns nearly to its original bronze colour on fusion or long-continued heating in the dark. By an exposure of thirty hours I have obtained on cyanin easily recognisable photographs of small, well-illuminated objects. A cyanin mirror, or better yet a piece of ground glass washed over with fused cyanin, exposed for ten hours to the spectrum of a Nernst lamp shows the effect to be very strong in the yellow, just perceptible in the adjacent red and green, and imperceptible in the blue and ultra-violet. It appears to correspond with the absorptive index as determined by Pflüger in various parts of the spectrum. At the same time, the exposure to light greatly decreases the absorbing power where it was originally large, as may be easily seen on looking at a sodium flame or a spectrum through an exposed coating of cyanin. It is as though the absorption were due to molecular resonance and the light produced a fatigue or destruction of this resonating power.

A most noteworthy change in the refractive index accompanies this change in the absorptive index, and is shown by the alteration in the reflecting power. The reflecting power of fresh cyanin is roughly 20 per cent. in the yellow, 2 per cent. in the blue-green and 6·5 per cent. in the ultra-violet. After exposure to light the reflecting power is nearly constant, 6·5 per cent., from the red out to $250\mu\mu$ in the ultra-violet. Now in the blue-green the absorptive index is so small as not to affect the reflecting power sensibly, so that the refractive index varies from about 1·1 to 1·6. Evidently work on the optical constants of cyanin is of little value unless carried on without exposure of the cyanin to daylight. A decrease in the absorptive index from 0·75 to nearly zero is indicated by the decrease in the reflecting power in the middle of the yellow, where exposure to light does not greatly affect the refractive index. The general effect of exposure to light is, then, to remove the absorption band and to destroy the characteristic anomalous dispersion.

The cyanin used was furnished by Kahlbaum, in Berlin, and is the ordinary diamyl iodide, $C_{29}H_{35}N_2I$, easily soluble in alcohol and ether, but only very slightly soluble in water.

Göttingen, August. P. G. NUTTING.

Fog Bow at Oxford.

A SOMEWHAT curious phenomenon, presumably an effect caused by the searchlights at Spithead, was visible here in Oxford on the night of Saturday last.

About 11.15 p.m., the night being fine and warm and the sky somewhat overcast, my attention was arrested by the appearance of an arc of whitish light, about 15° above the south horizon, within which the sky appeared of an intense black. The arc rapidly increased in elevation until, in six or seven minutes' time, it had reached the zenith, forming an arch extending, apparently, to the horizon on the east and west; it then declined northwards, and in another four or five minutes had vanished.

In appearance it suggested a brilliant lunar fog bow, but the light was of a more bluish tint, the interior circumference being far brighter than the outer; the brilliancy did not diminish to any great extent until the bow attained its highest altitude, after which it rapidly become fainter. The distance from Spithead is rather more than seventy miles. J. ROSE.

Rawlinson Road, Oxford, August 20.

Simple Means of Producing Diffraction Effects.

IN the interesting article on "Photography of Diffraction and Polarisation" published in the issue of NATURE for August 7, the writer describes various means of producing diffraction effects. It may possibly interest some readers of NATURE to know that beautiful fringes may be seen with even simpler apparatus than that described in the article referred to. All that is required is an ordinary folding foot-rule, preferably of ivory. To see diffraction bands by its means, it is only necessary to close the two halves of the rule until they are almost in contact and then to fold them over. On looking at the sun or other bright source of light through both slits, a series of brilliant diffraction bands will be seen. WILFRED HALL.

Tynemouth, August 20.

Time-Signals by Wireless Telegraphy.

MAY I suggest that the wireless telegraph offers a means of enabling Greenwich or other astronomical time being sent to ships at sea for the correction of their chronometers and the finding of their longitude? Distinct signals have already been transmitted from England to America, and these are all that is necessary for communicating time. At certain hours of the day or night, for example 1 p.m., a series of wireless signals, perhaps ten or twenty, at intervals of one second, might be sent from Greenwich far and wide as an extension of the time-ball signal which now serves for ships in the Thames and the Downs. By international regulation these time-signals could be protected from other wireless signals. I need scarcely add that such time-signals would also be useful inland. JOHN MUNRO.

Croydon, August 25.

THE BELFAST MEETING OF THE BRITISH ASSOCIATION.

SINCE the publication of our last article on the approaching meeting, the following additional arrangements have been made:—

The local executive committee (chairman, Sir Otto Jaffe) invites members, associates and holders of ladies' tickets to a garden party in Botanic Gardens Park, near Queen's College, on September 15, at 3 to 5.30 p.m.

In connection with this reception, the new fernery recently arranged by Mr. Charles McKim, curator of the Botanic Gardens, will be opened for the first time, and will be found well worth seeing by those interested in ferns and tropical plants.

On September 16, Lord O'Neill gives a garden party at Shane's Castle, picturesquely situated on the shore of Lough Neagh.

The Belfast Harbour Commissioners invite members, associates and holders of ladies' tickets to a reception in the Harbour Office on September 16, at 8 p.m.

Mr. and Mrs. John Brown will give a garden party at Longhurst on September 11 (by invitation). Their guests will be invited by Mr. G. Herbert Brown, J.P., to inspect St. Ellen damask and linen weaving works close by.

Mr. W. S. Bruce, of the Scottish Antarctic Expedition, has arranged that the exploring ship *Scotia*, recently fitted out, shall, before her departure, visit the harbour during the meeting for inspection by those attending it. The ship is elaborately supplied with instruments and apparatus for zoological, oceanographical and other branches of research, which will be in charge of her scientific staff. The inspection of the ship and her outfit will no doubt form a most interesting incident of the meeting.

Under the able management of Prof. Symington, good progress has been made with the loan exhibition, the following contributions to which will be found of special interest:—

From Mr. W. J. Knowles, a collection of specimens illustrating the various stages in the manufacture of stone implements collected from the remains of an ancient flint implement factory at Cushendal.

From Mr. R. Welch, a collection of Irish jaunting cars illustrating the development of that vehicle from a primitive form; also series of photographs illustrative of Irish ethnology, local geology and of the more special trade processes of the north of Ireland.

Irish ethnographical collections will also be exhibited by Dr. Scharff, Mr. S. F. Milligan, Mr. W. H. Patterson and Miss E. Davis.

The skeleton of the Irish giant is being kindly sent for exhibition from Trinity College, Dublin.

In connection with Section K (Botany), an interesting collection of Australian plants will be exhibited by Mr. Thomas Steel, as the representative of the Linnean Society of New South Wales.

Mr. R. Lloyd Praeger will exhibit a number of rare Irish plants.

The collection of apparatus employed by the late Prof. Andrews in his researches on the continuity of the liquid and gaseous states and on heats of combination, &c., is being carefully arranged by his daughter, Miss Mary Andrews.

Much private hospitality has been offered, but the large number of distinguished members who have signified their intention to attend has thrown considerable strain on the committee having charge of this department.

A forecast of the papers to be brought before most of the sections has already been given (August 7, p. 344; August 14, p. 377; and August 21, p. 397). We have now received the following list of papers arranged for the Section of Chemistry:—The president of the Section, Prof. E. Divers, F.R.S., is expected to take the atomic theory as the subject of his address at Belfast. A paper will be read by Dr. G. T. Morgan "On our Present Knowledge of Aromatic Diazo-compounds," and Dr. A. W. Crossley will give a paper "On Reduced Benzene Derivatives containing a Single Nucleus." The following papers, amongst others, will also be read:—"Present Synthetical Research on the Glucosides" and "The Synthetical Action of Enzymes," by Dr. E. F. Armstrong; "The Alkylation of the Sugars," by Prof. T. Purdie, F.R.S., and Dr. Irvine; "The Colour of Iodine containing Compounds," by Miss Ida Smedley; "On Zirconium Hydrate and other Colloids from Elements of the Fourth Group," by Dr. J. H. Gladstone, F.R.S., and Mr. W. Hibbert; "On some Optical Properties of Tellurium," by Dr. J. H. Gladstone, F.R.S.; "On the Telluric Distribution of the Elements in Relation to their Atomic Weights," by Mr. W. Ackroyd; "On the Undesirability of Establishing Standard Analytical Methods," by Mr. B. Blount; "On the Corrosion of Copper by Sea Water and on the Detection of Traces of Impurity in the Commercial Metal," by Dr. E. A. Letts; "On Experiments to Ascertain the Amount of Carbonic Anhydride from Sea Water by Air," by Dr. E. A. Letts and Mr. W. Caldwell; "On the Absorption of Ammonia from Water by Algæ," by Dr. E. A. Letts and Mr. J. S. Jotton; "On the Action of Distilled Water on Lead," by Dr. F. Clowes; "On the Decomposition of Urea," by Dr. C. E. Fawsitt.

The following description by Mr. R. Welch of the new path along the face of the Goban's Cliffs will be of interest to visitors.

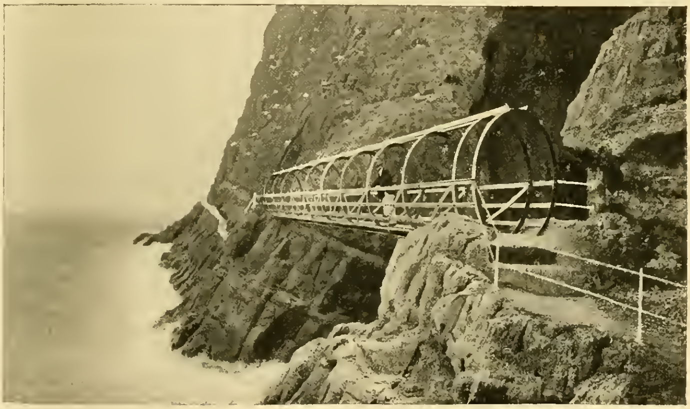

FIG. 1.—The "Goban's Cliffs" path at the Goban's Viaduct over the Man-o'-War Gully under the Gullery.

A Path around the Goban's Cliffs.

A fine cliff path along the base of the basaltic marine precipices near Belfast is now rapidly approaching completion; Mr. Wise, the engineer of the railway company—the B. and N. C. R., which is making the path under great difficulties—is putting forth every effort to have it ready before the British Association meets in Belfast. These mural cliffs of Lower Basalt lavas, in part semi-columnar, in part highly vesicular, with their many caves, will now for the first time be accessible to the geologist and the naturalist generally. At low tide many rock pools and natural aquariums will be available; some of these are coated with the pretty pink Lithothamnion, and have, like the pools of the Antrim Coast generally, a very varied fauna and flora. The path is carried over the many ravines at the mouths of caves by steel girder bridges; the troublesome wide gully at the "Man o' War" sea stack has been "negotiated" by a lattice girder, oval in section, 75 feet long, through which the path runs to the stack, thence by a flat girder bridge to the main cliff again.

Owing to the very heavy seas which sometimes break against the cliffs and run far up, the bridges have been set as high as possible; the "Goban's Lattice Bridge" is almost 30 feet above the sea. The path is tunnelled through one projecting spur of the cliff and runs through a long cave at another, while at the

"Seven Sisters" caves it will be carried by a suspension bridge of novel design, 200 feet long. At another place is a swing bridge, suggested by the famous rope bridge of Carrick-a-Rede; here it is no "rock in the road" of the salmon, but a deep gully into a wide cave, "in the road" of the climber. From the path, seals have been seen almost every day in early August; on one day porpoises were rolling about close inshore, and otters are known to have haunted the place from time immemorial. Some of the fish bones found in digging out a cave which was hidden by a great slip of basalt about forty years ago may be due to otters. Others of birds and mammals certainly are not, but have the appearance of the broken bones so plentiful in the prehistoric middens of Antrim and Down. These were found under from 400 to 500 tons of boulders, partly consolidated with earthy matrix, taken out of the cave, and are now in the hands of the Cave Fauna Committee investigating the Irish cave-deposits. The northern end of the path may not be completed this season, heavy gales having much delayed the work, and the tunnel which it will be necessary to excavate in hard rock at a place where the cliff overhangs very much will take some months to complete.

The first part of the path, that along the picturesque undercliff south of the cliffs section, was completed last year; there the Upper Chalk may be seen in large masses, broken up and slipping over the soft underlying Lias Clay, some sections of which are exposed, with, in a few places, good sections of Chloritic Chalk, Yellow Sands and Marls, and Glauconitic Sands. Details of these sections with lists of their fossil fauna will be found in Dr. Hume's classical paper on the Cretaceous strata of co. Antrim (*Q. J.* Geol. Soc., November, 1897, pp. 557–560, pl. xliv. and xlv.). The Basalts, I am afraid, have not received the attention here which they deserve, but now that these inaccessible cliffs, tier upon tier of thin lava flows weathering in the most varied manner, can by this new path be easily reached from the land, it is to be hoped they will be visited by many geologists in the near future. The *Memoir* of the Geological Survey, Ireland, No. 29, gives a brief description of them, with section at south termination. One may dine in London or Manchester, and by the short sea route *viâ* Stranraer breakfast in Larne or Whitehead, and be right under these cliffs long before noon. Mr. Wise has kept well in mind the motto of the Belfast Field Club, of which he is a member, "Preservation, not Extinction," and the herring gulls which nest along the cliffs here in large numbers were disturbed as little as possible; some even nested on the partly made path. He has been careful to preserve the natural-weathered surface of the rock all along the path; it has only been broken where absolutely necessary for safety, and geologists are kindly requested to follow this example. They will find abundance of good material quarried out at many places quite close to the path, including good samples of the vesicular portions of the flows, with the original vesicles now filled with various zeolites.

R. WELCH.

A GREAT PERSIAN TRAVELLER.[1]

THE fascination which countries "old in story" exercise on many minds is more easily recognised than explained. But the existence of this fascination being once admitted, it is not difficult to understand why a peculiar glamour should attach to Persia, a land of which the history extends almost as far back as any authentic record of the human race, other than that derived from fossil bones or implements, can be said to exist. Nor is this the only attraction which Persia possesses, for although it is inhabited by the most civilised people of Asia, the greater portion of the Persian plateau was, until the last thirty years of the nineteenth century, almost unexplored by Europeans, and even at the commencement of the twentieth century no railway has crossed the Persian frontier, and the only road constructed for wheeled carriages, that from Resht to Teheran, is of no great length and is said to be in bad condition. In many respects the Persia of the present day resembles western Europe three hundred years ago, or perhaps in some respects even earlier. The general mode of travel is on horseback, the traveller's baggage and all merchandise are carried on pack animals, the roads are insecure and robbers abound. Even in the latter half of the nineteenth century, in eastern Persia and Baluchistan, raids by armed bands were of common occurrence, whilst less than thirty years ago Turcoman hordes from the north swept over northern Persia as far as the gates of Yezd and Isfahan, and murdered, plundered or dragged away as slaves the unfortunate inhabitants whom they encountered. Almost to this day the history of the tribal chieftains and of the provincial governors in eastern Persia and Baluchistan resembles that of European princes in the middle ages, when it was a rare exception for any man of note to live or die peaceably.

But a great change is gradually being effected in Persia, as in so many other countries. The Turcoman forays were summarily ended by Skobeleff's sweeping destruction of the raiding clans at Geok-tepe, a consummation aptly compared by Major Sykes to the more recent annihilation of the Soudanese slave-drivers at Omdurman. The "chapaos" of the Baluchis have been checked by the division of Baluchistan between Persian and British rule, and the frontiers between Afghanistan, Persia and British Baluchistan have been defined and mapped. The central government in Persia has gained power, and has been able during the last half century, despite many shortcomings, to do something for the protection of the people and the encouragement of agriculture and trade.

The author of "Ten Thousand Miles in Persia" has consequently had the advantage of studying the country at an interesting time. Few of the travellers in Persia since the time of Alexander the Great have had better opportunities or been better qualified than Major Sykes, who is an energetic explorer, a good linguist and a sympathetic student of Persian life and history. Several portions of his travels in eastern Persia and Baluchistan have already been briefly described in the *Geographical Journal*, but fuller accounts are given in the present work, together with numerous notes on the physical geography, history and people of the countries traversed. The various journeys of the author are not confined to eastern Persia. At one time or another he has traversed all the principal routes, including the well-known road from the Persian Gulf to the Caspian by Shiraz, Isfahan and Teheran; but, as he points out in his preface, he has touched but lightly on the provinces and cities of Persia that were fully dealt with in Lord Curzon's work, and has chiefly treated of those parts of the country, in eastern Persia and Baluchistan, that were previously less well known. A very large part of the book treats of journeys and researches of various kinds in the province of Kerman and in Persian Baluchistan, but in the execution of consular duties interesting visits were made to Sistan and Kain in one direction, and to the Persian Gulf, Basra (Bussorah) and Shuster in the other.

The additions made by Major Sykes to our knowledge of the geography of eastern Persia and Baluchistan are numerous, and they have in many cases greatly changed the map. For instance, by ascertaining that the stream flowing past Bampur does not reach the sea by the Rapsh, but is, like so many other Persian rivulets, evaporated in a "kavir," or salt marsh, he has added at least 20,000 square miles to the Persian inland drainage area, from which no water flows to the ocean. He has also aided materially in completing the investigation of the great desert region of Khorassan, called Dasht-i-Kavir or Dasht-i-Lut in maps. He shows that the name

[1] "Ten Thousand Miles in Persia, or Eight Years in Irán." By Major Percy Molesworth Sykes (Queen's Bays), H.M. Consul, Kermán and Persian Baluchistan. Pp. xv + 481; with numerous illustrations and map. (London: John Murray.)

of Lut by itself is that generally used in the region, and that this name is identical with the scriptural Lot. It may be remarked that in some cases the views put forward by Major Sykes as to the origin of geographical terms differ from those of his predecessors. This is especially noteworthy in the case of Makrán, the well-known name for the Baluch seaboard. Instead of adopting Sir T. Holdich's explanation that the term is derived from *Mahi-Khuran*, or fish-eaters, the Ichthyophagi, as the inhabitants were called in the days of Alexander the Great, Major Sykes looks upon it as connected with the people once known as Maka, the Mykians or Mycæans of Herodotus.

One of the most interesting tracts examined by Major Sykes is the Sarhad, or cold country, of Persian Baluchistan. A large portion of the population of Persia consists of wandering tribes, who pass the winter in a Garmsir or warm tract, and drive their flocks and herds in summer to a Sarhad or more elevated region. The Baluch Sarhad had only been visited by one traveller before Major Sykes entered it, and it is remarkable for including within its limits two extinct and dormant volcanoes, the Kuh-i-Basmán, 11,000 feet high, and the Kuh-i-Taftán, more than 12,000 feet, both of which were ascended. There is a great area covered by volcanic formations in south-eastern Persia, the lofty peaks of Kuh-i-Hezar and Kuh-i-Shah, south of Kerman, consisting, in part at all events, of basalt and similar rocks, although these mountains are certainly not volcanoes of recent origin, like those of the Baluchistan Sarhad, some 200 miles further west. Major Sykes, however, is not a geologist, and adds but little to our information on this point, although he ascended and measured both the great peaks south of Kerman, which rise to between 13,000 and 14,000 feet.

Amongst the principal historical questions on which fresh light is thrown by the present work are the travels of Marco Polo and the remarkable march of Alexander the Great, with an army, through Baluchistan, from the Indus to Persepolis. This march, one of the most extraordinary military enterprises ever undertaken, must always remain a puzzle to all who have any acquaintance with the country traversed, for a more hopeless desert than the greater part of Makrán at the present day does not exist. In reference to this march, and to the remains of ancient cities and the evidence of abandoned cultivation in so many parts of Persia, Major Sykes supports the view already adopted by many other travellers in Persia and in Central Asia generally, that the whole area is undergoing gradual desiccation, and that the rainfall must have diminished considerably in the course of the last two or three thousand years. This view has recently been strongly enforced by Mr. Vredenberg's interesting observations in Baluchistan, of which an account has appeared in the *Memoirs* of the Geological Survey of India (vol. xxxi. pt. 2). The diminution of the rainfall may be connected with the disappearance of certain great Central Asiatic lakes, of which important remnants exist in the Caspian and Aral Seas. In one passage Major Sykes is inclined to attribute the diminished rainfall to the destruction of forests, and even appears to believe (p. 365) that India, if all the forests were swept away, would become as barren as Persia. This is rather an exaggerated view. The destruction of every tree in

Fig. 1.—Makrán Scenery.

India would not prevent the rain of the south-west monsoon from falling, although it might somewhat diminish the amount, and it would in other ways seriously affect the fertility of the country. It may fairly be doubted whether, at all events within the last three thousand years, anything deserving the name of forest existed in eastern Persia.

The numerous illustrations in the present work, chiefly reproduced from photographs, convey an excellent idea of the barren Persian and Baluchistan hill scenery and of Persian towns and people. On the whole the scenery of Baluchistan, and especially of Makrán, of which two examples are here given, is perhaps better depicted than are the plains of Persia. The enormous distances to which these plains extend probably preclude their effective representation by photographic means, but it is remarkable that none of the views, numerous and varied as they are, gives any idea of one of the most striking characteristics of Persian scenery, the gravel slopes, often many miles wide, that surround nearly all the great plains and often occupy the broad valleys that extend from the plains far into the hills. As the waterless plains themselves are often, in parts, occupied by "kavir" or salt marsh and in other parts by drifting sands, whilst the broken hill-ranges that cross the country are only passable in places, it is on the gravel slopes that the principal trade routes run, and it is in them that are tunnelled the "kanauts" or "karezes," the artificial subterranean channels from which the water-supply for towns and for irrigation is largely derived. Throughout the Persian plateau these slopes are a most striking feature; they are seen from Teheran, north of which city one, on a large scale, extends to the Elburz Mountains, to Quetta, where, east of the town, there is a well-marked glacis-like slope on a smaller scale.

Major Sykes is no zoologist, and it is therefore not surprising that some of the names of animals to which he refers require alteration. It is not quite correct to call the Persian wild goat an ibex, a term belonging to goats with very different horns; but a greater mistake is made in the foot-note at p. 47, where it is stated that "the Jabal Báriz range separates the habitat of the *Gazella Benetii* (it should be *Bennetti*) from that of the *Gazella fuscifrons* of the plateau of Irán." The gazelle of the "plateau of Irán" is *G. subgutturosa; G. fuscifrons* is a variety of *G. Bennetti*. Again, on p. 289 an amusing account is given of the capture of a *hake* at the island of Hormuz, in the Persian Gulf. The hake is a fish peculiar to the North Atlantic.

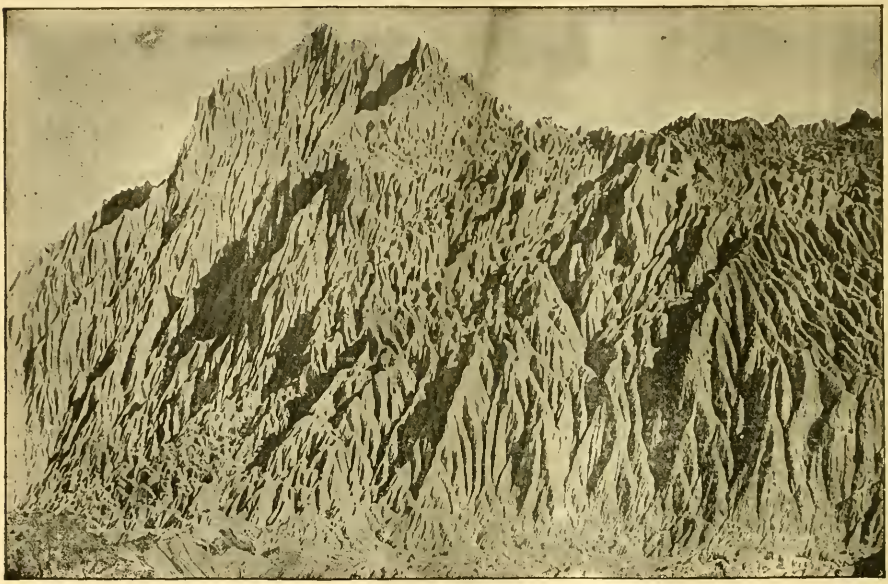

FIG. 2.—Clay Formation, Makrán.

But if Major Sykes's pages add but little to our knowledge of geology, botany or zoology, they abound in fresh information concerning the curious mixture of Asiatic races which inhabits the wilds of Baluchistan, on the physical geography of the eastern Persian area and on the history of the towns and provinces. The author's views as to the political relations existing between Persia and our Indian Empire are of importance as expressing the opinions of an officer who has had exceptional opportunities of forming an accurate judgment. In one respect Major Sykes has proved himself a model diplomatist, for he appears to have succeeded in establishing friendly relations with almost all the officers of the Persian Government with whom he came in contact.

W. T. B.

NOTES.

EARLY in this year a petition praying for the incorporation of a British Academy for the Promotion of Historical, Philosophical and Philological Studies was presented to the King, and referred to a committee of the Privy Council. Acting upon the advice of this committee, His Majesty has granted the Academy a Royal Charter. The Charter has not yet been published, but according to the *Times* it states that the Academy aims at "the promotion of the study of moral and political sciences, including history, philosophy, law, politics and economics, archæology and philology." The forty-nine first fellows of the British Academy include leading representatives of many branches of scholarship, but not of poetry or fiction or other departments of pure literature. The Academy will be an independent body, with a separate organisation of its own; and it will not have any closer relationship to the Royal Society than has the Royal Academy of Arts. Our institutions for the advancement of learning and the development of intellectual activity will not, therefore, be coordinated in the way they are in France and several other countries.

THE following reports of eruptions and earthquake shocks have been published during the past few days:—*August* 21.—Severe eruption of Mont Pelée reported by the steamer *Dahomé* to have occurred at noon. No confirmation of the news has reached the French Colonial Office. *August* 22.—Mont Altomonte in Calabria reported from Rome to be in eruption. Subterranean rumblings have been heard, and showers of rock fragments and vapour have been ejected from the crater. An unusually large earthquake was recorded at Shide, in the Isle of Wight. The movement commenced at 3h. 10·9m. a.m. Twenty-five minutes later the amplitude of the large waves exceeded 22 mm. (12″·0). The time interval suggests an origin about 62° distant from the Isle of Wight. Origins for world-shaking earthquakes at this particular distance are Alaska, the West Indies and northern India. Sixty-seven minutes after the maximum movement, but long before its irregular group of followers had ceased to exist, a second group of large waves appeared, the amplitudes of which were 18 mm. (9″·0). The seismographic instruments at observatories in Hungary and Alsace registered several earthquake shocks in the direction from east to west in the afternoon. Two violent shocks were felt at Andishan, and one at Pavlovgk, near St. Petersburg. *August* 25.—Messages from Dominica report that between 10 a.m. and 3 p.m. clouds of dust were seen in the direction of Mont Pelée, while detonations were heard at long intervals until morning. Light showers of volcanic dust fell in Dominica.

DR. L. A. BAUER contributes to *Terrestrial Magnetism and Atmospheric Electricity*, vii. 2, a note on his observations of the magnetic disturbances which occurred during the eruption of Mont Pelée on May 8. At 11h. 59m. a.m., Greenwich mean time, a disturbance occurred which began simultaneously at the two Coast and Geodetic Survey magnetic stations of Cheltenham, Maryland and Baldwin, Kansas. The time of these disturbances was the same as recorded at other observatories, and corresponded to 7h. 54m. of local time at St. Pierre, being about the time at which the principal clock of that town was stopped. The horizontal intensity was the element principally disturbed, and the suddenness with which the disturbance of May 8 began is well illustrated by Dr. Bauer's horizontal intensity curve. Several interesting magnetic disturbances also occurred between April 10 and May 8, possessing striking similarities with each other and with that of May 8, these similarities, both in magnitude and direction, extending to all three elements. During the eruptions, Dr. Bauer observed perturbations of greater or less degree, another striking coincidence occurring on May 20 at the second eruption.

THE nomination of Lord Rayleigh as foreign corresponding member of the Vienna Academy of Sciences has just been confirmed by the Emperor Francis Joseph.

A NUMBER of eminent surgeons representing many countries will be present at the Congress of the Belgian Society of Surgery, to be held at Brussels on September 8–11, when a proposal will be made to found an international society of surgery.

MRS. R. W. LONGFIELD writes from Bandon, co. Cork, Ireland, to say that on August 18 she heard the cuckoo's note distinctly near Bandon. The cry of cuc-koo was repeated several times.

THE address by Sir Archibald Geikie, which we are able to print in full in another part of the present issue, was delivered before a large audience at Cromarty on Friday last, in connection with the celebration of the centenary of Hugh Miller. Many eminent men from America, Canada and Italy, as well as from various parts of the British Isles, assembled to do honour to Miller's memory and to testify to his inspiring influence. The oration delivered by Sir Archibald Geikie was worthy of the occasion, and the eloquent words in which Miller's life and work were described will be read with as much pleasure as they were listened to by the audience privileged to hear them. Among other speakers at the open-air meeting near Hugh Miller's monument, and at the subsequent luncheon, were Principal Rainy, Prof. Clarke, Albany, New York; Sir James Grant, Canada; Dr. Horne, F.R.S., and Prof. Middleton.

IF we may judge from the rarity of reports, the sound of the salutes during the naval review on August 16 does not appear to have been heard at any unusual distance. Mr. H. F. Pinder, writing from Blackbourton, near Bampton, informs us that the salute at 2 p.m. was heard by one, but so far as he knows only by one, person. Earlier on the same day, between 11.30 and 12.15, heavy firing was heard, apparently from the south-south-west, the sound being continuous during the first half-hour. The distance of Blackbourton from Spithead is about 70 miles.

WE learn from the Berlin correspondent of the *Times* that the German Sea Fisheries League recently organised a scientific expedition to ascertain the value of deep-sea fishing in the Baltic. The league, with the assistance of the Ministry of the Interior, chartered the Kiel steamer *Holsatia* and fitted her out for trawl fishing and for scientific investigations. It was also intended to experiment with a view to discover how far the type of boat and the methods of fishing at present in use on the Baltic coast would prove suitable in the open sea. The report has not yet been published, but it appears that no large feeding grounds have been found, and that trawl fishing such as that practised in the North Sea would not pay in the Baltic.

THE thirteenth annual general meeting of the Institution of Mining Engineers will be held at Newcastle-upon-Tyne on September 17–19, under the presidency of Mr. J. S. Dixon. Among the papers to be read, or taken as read, are the following:—On the probability of finding workable seams of coal in the Carboniferous Limestone or Bernician formation beneath the regular Coal-measures of Northumberland and Durham, with an account of a recent boring made at Chopwell Woods, near Lintz Green, Mr. J. B. Simpson; notes on the correlation of the beds of the Carboniferous series in the north-east and north-west of England, Mr. David Burns; the Marl-slate division of the Permian, Prof. G. A. Lebour; steam-generation by the gases from Beehive Coke-ovens, Mr. M. R. Kirby; and the Fernie coal dust explosion, British Columbia, Mr. William Blakemore.

A NOTE on the progress of the Swedish South Polar expedition appears in the *Times*. The vessel *Antarctic*, with five scientific members of the expedition, left Port Stanley, in the Falkland Islands, on April 11 for South Georgia, U.S.A. The expedition

stayed in South Georgia from April 22 to June 15, and during this time a detailed survey was made of Cumberland Bay, one of the largest bays in South Georgia. Investigations into the natural history of Cumberland Bay were carried on, and zoological collections brought home from depths as great as 2700 metres. Soundings have given depths up to 5997 metres north-west from South Georgia. The expedition returned to Port Stanley on July 4, and will up to the end of September carry on work around the Falkland Islands and in Tierra del Fuego. In October, the *Antarctic* will start for Graham Land, in the Antarctic Ocean.

THE United States National Museum has just issued a printed list (24 pages) of the meteorites acquired for the Washington collection before January 1, 1902. The list, which is intended mainly to facilitate exchanges and the increase of the collection, is alphabetically arranged, and gives for each of the meteorites the weight in grams, the date of fall or find, and a brief description of the more salient characters. As many as 348 falls are represented, 143 being those of meteoric iron. There are three full-page plates, photographic reproductions; one illustrates the arrangement of the specimens for exhibition, while the two others are pictures of the Allegan and Casas Grandes meteorites. The list has been prepared by Mr. Wirt Tassin, assistant curator in the Division of Mineralogy.

IN vol. xxiv. of the *Proceedings* of the United States National Museum, Mr. G. P. Merrill gives a detailed description of fragments of a meteorite ploughed up some years ago at Admire, Lyon County, Kansas, U.S.A. As the metallic part is much rusted, probably a long interval of time elapsed between the fall and the find of the material. The meteorite, of which about 44 lb. weight is known to have been collected, belongs to the same group as the iron brought by Pallas from Siberia (1749), but approximates more closely in characters to the meteorite found in 1880 at Eagle Station, in Kentucky. It consists of a continuous mass of meteoric iron enclosing angular crystals of olivine (1 to 30 millimetres in diameter), the crystals having been in almost every case broken and afterwards cemented together by metallic material which had flowed into the fissures. Schreibersite, troilite and also small grains of chromite are comparatively abundant as constituents of the metallic portion, which forms about one-third of the whole mass.

ALASKA would seem to offer opportunities to the bryologist as well as to the gold-seeker. Although several collections of mosses have been made in that country from the year 1867 to the present time, Mr. J. Cardot and Mr. I. Thériot have placed on record twenty-nine new species as the result of collections made by the Harriman expedition in 1899. The descriptions of these, together with a general list of all known mosses from Alaska, are given in the *Proceedings* of the Washington Academy of Sciences bearing the date July 31 of this year. This does not, however, include a collection of more than 200 mosses which have been identified and named by Mr. R. S. Williams since this paper was written. The new species, which are given on the authority of the writers, except most of the Bryum species, for which M. Philibert is responsible, are fully diagnosed and illustrated. In addition, seventeen new varieties are recorded, and *Bartramiopsis Lescurii* is described in full with figures.

IT is not the happy fate of many botanical gardens to be able to put by a surplus of more than 1000*l.* in one year. Such is the announcement which appears in the thirteenth annual report of the Missouri Botanical Garden. The director, Dr. Trelease, presents his report, and in addition a memoir on the tribe Yucceæ of the order Liliaceæ. The latter is the result of a study extending over sixteen years, during which time large numbers of varieties have been examined in their native habitats and certain of them have been taken into cultivation. As this tribe is preeminently American, and in fact almost confined to the United States, and as the writer has taken advantage of every available opportunity to examine interesting or critical specimens, the results and opinions here recorded are extremely valuable. Very interesting by reason of the ordinary dependence of these plants upon the Pronuba moth for pollination is the reference to hybrids which have been raised. It will be noticed that one of the parents in many cases is *Yucca aloifolia*, this species being unique since it is usually self-pollinated. To the two genera Yucca and Hesperaloe, which are combined by Engler, is added a third genus, Samuela, with two species, instituted by Dr. Trelease; also the genus Yucca of Dr. Engler is split into three genera, Hesperoyucca, Clistoyucca and Yucca. The memoir is lavishly illustrated with more than one hundred figures reproduced from photographs.

THE Imperial Engineering Company, of Liverpool, has issued a pamphlet descriptive of apparatus for illustrating Prof. Hele Shaw's experiments on stream-line motions, both for use in schools and colleges and for original research.

A BRIEF account of the bibliography of Gilbert's "De Magnete" is given by Herr G. Hellmann (Berlin) in *Terrestrial Magnetism and Atmospheric Electricity*, vii. 2. It appears that only three editions of this work appeared, namely, Londini 1600, Sedini 1628, and Sedini 1633. Of the Sedini 1628 edition two varieties are known, differing in their title-pages. The rarest edition is the Stettin one of 1628, and of the two varieties that is rarest which has on its title-page the words "*Sumptibus | Authoris*|.'

A NEW journal has been started in Glenville, U.S.A., bearing the title *The Aeronautical World*, and dealing with matters relating to aërial navigation of all kinds. It contains a large number of notes on events of current interest in this connection, lists of patents, and other information of this class. We should like to see rather more attention given to the difficulties which have still to be surmounted in connection with the problem of flight, leaving writers like Mr. H. G. Wells to indulge in "anticipations" of a speculative character as to the future of aërial navigation when these difficulties have been overcome. Still, such speculations have a certain attraction for those who cannot appreciate anything but accomplished results.

THE *Comptes rendus* of the Paris Academy of Sciences (July 21) contains a report on a paper by M. Torres dealing with a project for a navigable balloon with an interior keel. The idea contained in this project is very similar in general principle to that underlying M. Severo's ill-fated machine, namely, to bring all the forces acting on the balloon into the same horizontal line, with a view of minimising pitching. Accordingly M. Torres proposes a balloon with several compartments, containing a central beam suspended in its interior, and forming, with its attachments, a rigid internal keel. The propeller will then be attached at the end of this beam, and the car, which is to be reduced to the smallest possible dimensions, will be close up to the balloon. The fatal *Pax* disaster, however, raises doubts in regard to the last feature.

AN astronomical model called the "Rotaplane," devised by the Rev. C. Thomas and provisionally patented by him, has been submitted to us for examination. The model is intended to show the apparent diurnal motion of the horizon of any latitude with reference to the ecliptic at any time of the year. The direction of the polar axis is represented by an upright rod, to which the horizon can be inclined at an angle equal to the latitude of the desired place of observation. A semi-meridian is fixed to the horizon, and outside the whole is a flat ring to represent the plane of the ecliptic. By turning the polar axis, after

setting the ecliptic at the correct inclination, the diurnal movement of the horizon with reference to the sun or other object in the ecliptic can be made manifest. An objection to the model as an educational instrument is that the horizon is only horizontal when the latitude for which it is set is 90°. The student of astronomy who understands the relationship between the fundamental planes of the horizon, equator and ecliptic might find it an advantage to fix his ideas by means of a model of this kind. But such a student would be in a position to use a celestial globe by which he could see the apparent motions, with reference to the horizon, of objects in any part of the celestial sphere instead of being limited to the ecliptic.

THE twenty-fourth Report of the Deutsche Seewarte, Hamburg, for the year 1901, exhibits the usual activity in the various pursuits in which the institution is engaged. Several meetings have been held at Berlin and Hamburg with the view of improving and expediting the telegraphic weather reports. In this most important object andin the establishment of a 7h. a.m. service, several of the European countries are to some extent participating, but the movement is due mainly to the impulse given to it by the Deutsche Seewarte. The sum of six thousand marks has been placed at the disposal of Dr. von Neumayer for the purpose of establishing special weather forecasts for agriculturists, probably on the same lines as those for the harvest forecasts issued by our own Meteorological Office. The collection of observations made at sea, for the construction of sailing directions and meteorological handbooks of the various oceans, has been vigorously carried on. Complete log-books were received during the year from 60 men of war and 538 merchant vessels, in addition to some 300 short logs from steamers. The majority of the voyages refer to the north and south Atlantic, but also include a considerable number in the Pacific and Indian Oceans. Telegraphic warnings of storms were issued on fifty-nine days; the number of telegrams (including those to lower the signals) exceeded 3000, but the percentage of success is not stated.

EXCLUDING the well-known thermophilic group of bacteria, it has generally been considered that an exposure to a temperature of 65° C., or frequently to a lower temperature than this, is rapidly fatal to all non-sporing forms of bacterial life. Messrs. H. L. Russell and E. G. Hastings, however, describe a micrococcus, isolated from milk, the thermal death point of which is 76° C. for an exposure of ten minutes. Not all the cells of this organism are equally resistant; as the temperature is raised to about 70° C. some of the cells begin to succumb, but a small residuum retain their vitality until 76° C. is reached (*Centr. f. Bakt., Zweite Abt.*, Bd. viii. p. 339). Using this organism, Messrs. Russell and Hastings have carried out some interesting observations upon the increased resistance of bacteria in milk pasteurised in contact with the air (*ib.*, p. 462). Heated in bouillon and in milk in closed vessels (sealed tubes) the thermal death point is approximately the same, viz. 76° C., but in milk heated in an open vessel the organism survived a temperature of 80° C. It was found that this resistance is due to the protection afforded by the membrane which forms when milk is heated freely exposed to the air, for in samples of sterile milk seeded with the organism and heated in an open beaker to 80° C., on subculturing numerous colonies were obtained from the membrane, while the milk below this was sterile.

SURRA, a disease affecting horses and other animals, and due to a protozoan parasite, the *Trypanosoma Evansi*, has been found to be very prevalent in the Philippines, causing the death of no less than 2000 of the army transport and cavalry horses in a period of six months. This disease, met with also in India and Burma, is now regarded as identical with nagana or the tsetse-fly disease of Africa. In India, the exact mode of transference of the disease from one animal to another has not been discovered, though certain "horse-flies" have been surmised to be the intermediaries. In the Philippines, Curry states that the intermediary is a fly, the *Stomoxys calcitrans*. The fly lays its eggs in the excrement of horses and cattle, in which its larvæ and pupæ thrive, and as the disease is almost always fatal, prophylactic measures must be employed, especially the destruction of the larvæ and pupæ in the excrements by treatment with lime or petroleum (*Amer. Med.*, July 19).

THE *Zoologist* for August contains notes on Erasmus as a naturalist, by Mr. G. W. Murdock, and a useful account by Mr. G. Smith, of Prof. Bachmetjew's experiments on the temperature of insects.

WE have received a copy of the first number of the *Rural Studies Series*, which contains the report of a lecture by the Rev. E. A. Woodruffe-Peacock on the manner in which horses —especially thoroughbreds—affect the grass-lands on which they are pastured, and the best manner of improving such pastures.

THE *Memorias* of the Scientific Society Antonio Alzate, vol. xvi., Nos. 5 and 6, contain an account, by Señor A. L. Herrera, of the means recently taken to mitigate the plague of mosquitoes from which the city of Mexico constantly suffers. A couple of men provided with tins of paraffin appear to have done wonders in the way of destroying the larvæ which infest the pools and sheets of water in the suburbs.

IN its report for the year 1901–1902, the committee of the Manchester Museum directs attention to the highly satisfactory and commendatory remarks on that institution and its work which appear in the Blue-book recently issued by the Commissioners on the University Colleges of the country. Among the collections received during the year is a fine series of shells presented by Mr. R. D. Darbishire, containing a number of rare forms and also examples of the range of variation presented by particular species. The lectures and addresses delivered during the year have proved attractive to the general public, and will be continued during the current session, when Prof. Hickson will discourse on reptiles, Prof. Weiss on club-mosses and ferns, and Prof. Dawkins on caves.

THE geology and petrography of part of the Ural region of Perm, in the upper basin of the Koswa, a tributary of the Kama, has been elaborately dealt with by MM. Louis Duparc and Francis Pearce (*Mém. de la Soc. de Physique de Genève*, xxxiv. 1902). In particular, the gabbros and dunites of Koswinsky are described, but there are also full accounts of the orography and hydrography of this region.

IN the *Papers* and *Proceedings* of the Royal Society of Tasmania for 1900–1901, a great many subjects are dealt with, including some useful general articles on the botany, the birds, the recent Mollusca, the minerals and the geology of Tasmania. In notes on the microscopic structure of some Tasmanian rocks, Mr. W. F. Petterd describes some aberrant members of the basalt family. Mr. W. H. Twelvetrees describes a new oxychloride of lead, under the name Petterdite. There are notes also on the discovery of amphibian remains in the permo-Carboniferous rocks.

WE have received the annual report for 1901 of the Geological Survey of New Jersey, by Mr. H. B. Kümmel, acting State Geologist. He refers to the fact that New Jersey is the chief clay-producing State, and that a new and exhaustive memoir of the clay deposits is in preparation. The report is accompanied by a memoir and map of the Green Pond Mountain region, a belt of Cambrian, Silurian and Devonian rocks which rest on an eroded surface of gneisses. There are notes on the

iron, zinc and copper mines, on various artesian wells, and on the presence of chlorine in certain natural waters. It is recommended that the State authorities should conserve all watersheds likely to be drawn upon in future by large towns.

THOSE who attended the meeting of the Geological Society of London on January 8 were impressed with the lucid explanations of Glacial phenomena in the north of England then given by Prof. Percy F. Kendall and Mr. Arthur R. Dwerryhouse. Their observations recently published (*Quarterly Journal* Geol. Soc. for August) constitute most valuable contributions to the study of the Great Ice Age in this country. Prof. Kendall deals with the Cleveland Hills, and points out the evidence there existing of the former occurrence of a number of glacier-lakes or "extra-morainic" lakes, such as are produced whenever a glacier or ice-sheet advances against or across the general slope of a country and impounds the natural drainage. Evidence is given of such lakes of large and small dimensions in the Vale of Pickering, in Glaisdale and Eskdale, in Harwood Dale and at Hackness, lakes which must have been formed when the ice occupied the Vale of York and extended along the northern and eastern borders of the Cleveland area. The evidence is furnished by shore scarps, occasional lacustrine deltas with fan-like forms, by laminated lacustrine deposits such as the warp clays of the vales of Pickering and York, by overflow channels whence the impounded water escaped in gorges which trench the main watershed or sever spurs independent of the present natural drainage, and by crescentic valleys excavated in the face of a hill by water flowing round a lobe of ice. The Glacial deposits are, of course, fully considered from sections and from borings, some of which were carried out by Prof. Kendall. The assemblages of boulders and rock fragments lead to the conclusion that three main ice-movements affected the area—a northern from Scotland and Northumberland, a western from Stainmoor Pass and the Tees valley, and an eastern from the North Sea and Scandinavia. The general sequence which may be inferred from a study of the somewhat complicated phenomena is (1) the unobstructed passage of the Teesdale glacier to the coast; (2) the arrival of the Scandinavian ice; and (3) the invasion of the Scottish ice. The author finds no signs of the presence of the sea in the Cleveland area at any time during the Glacial period. Mr. Dwerryhouse describes the glaciation of Teesdale, Weardale and the Tyne valley, a region in which, like that of Cleveland, the higher tracts stood out as "nunatakkr," while the grounds beneath were buried by ice. He also points out that at the period of maximum glaciation a number of lakes were formed, owing to the obstruction of the drainage of lateral tributary-valleys by the ice of the main glaciers.

DRS. H. M. HILLER and W. H. Furness have privately issued bound copies of the "Notes of a Trip to the Veddahs of Ceylon," which were published in vol. iii. of the *Bulletin* of the Free Museum of Science and Art, Philadelphia (April, 1901). The "Notes" do not contain much that is new, but they are illustrated with several excellent photographs, the most interesting of which are those illustrating a Rock Veddah shooting (standing) with a bow and arrow, and one making fire with a "fire-drill."

THERE is in *The Reliquary and Illustrated Archaeologist* (vol. viii. No. 3) a well-illustrated article, by Mr. R. Quick, on the Carib stone implements in the Horniman Museum. These implements show the technical skill of the aborigines of the West Indies in working hard rock. Some of the implements are really remarkable examples of stone-work. One example which is figured has a most irregular contour; from its high finish it was evidently greatly prized, and was probably a symbolic religious object, of which the significance is at present unknown.

The early Christian monuments of the Isle of Man are becoming well known to students through the enthusiastic labours of Mr. P. M. C. Kermode. In the July number of *The Reliquary and Illustrated Archaeologist* he gives numerous illustrations of recently discovered crosses and runic and ogam inscriptions. One of the most interesting discoveries is a carved stone with very characteristic Scandinavian interlacing; on one side is seen the figure of Loki in the act of heaving stones at the otter which is eating the salmon it has just caught in the foss; above this is the steed Grani with the chest containing the hoard won by Sigurd upon his slaying the dragon Fafni.

MESSRS. PERKEN, SON and Co. have issued a new revised and enlarged edition (the eighth) of their "Beginner's Guide to Photography." The book is now in its seventieth thousand.

IN the article on "The Older Civilisation of Greece," which appeared in NATURE of August 21, the following corrections should be made:—P. 391, *col.* 1, *l.* 9 from bottom: *for* "the un-Aryan 'Pelasgian'" *read* "the probably un-Aryan 'Minoan'"; p. 393, *col.* 2, *l.* 12 from top: *for* "ἐν μυχῷ, Ἄργεος" *read* "ἐν μυχῷ Ἄργεος"; *ibid.*, *l.* 14 from top: *for* "casements" *read* "casemates"; p. 394, *col.* 1, Fig. 2: *for* "Clay Seal. Impression" *read* "Clay Seal-impression."

A MINUTE investigation of the composition of Pennsylvania petroleum has recently been carried out by Mr. C. F. Mabery, and an account of the hydrocarbons with boiling points above 216° C. is published in the *Proceedings* of the American Academy of Arts and Sciences (vol. xxxvii. p. 565). Hydrocarbons of the methane series from tridecane $C_{13}H_{28}$ to octocosane $C_{28}H_{58}$ have been isolated, and according to the molecular-weight determinations carried out by the freezing-point method the products obtained by the author as the result of repeated fractional distillation under low pressure are almost pure. No account appears to have been taken, however, of the possibility of the occurrence of different isomeric forms. In addition to these saturated compounds the hydrocarbons $C_{22}H_{44}$, $C_{23}H_{46}$, $C_{24}H_{48}$, $C_{26}H_{52}$ and $C_{27}H_{54}$ belonging to the ethylene series and $C_{28}H_{54}$ a homologue of acetylene, have been obtained.

MUCH remains to be learnt about the numerical relationships of the atomic weights of the elements. It has long been realised that when referred to the standard $O = 16$ many of the atomic weights approach whole numbers to an extent out of all proportion to the probabilities of the case. In the *Chemiker-Zeitung* for July 19, Mr. Arthur Marshall, as well as directing attention to this fact, shows that very remarkable relationships exist in many cases between the atomic weights of allied elements. Taking from the tables of the German Chemical Society the eighteen values given to two places of decimals, the theory of probabilities shows that the chances against their approaching as close as they do to whole numbers are as high as 4120 : 1. If, on the other hand, the atomic weights are referred to $H = 1$, there appears to be little or no tendency to become whole numbers. It is, however, only when certain of the atomic weights are referred to entirely different standards that the most striking relationships appear. The weights of the atoms of the halogen elements and silver, for instance, are exactly in the ratio $Cl : Br : Ag : I = 90 : 203 : 274 : 322$. In the case of the alkali metals the proportions are even simpler, $Li : NH_4 : Na : K : Rb = 7 : 18 : 23 : 39 : 85$. Again, the horizontal series, $V : Cr : Mn : Fe : Ni : Cu : Zn = 54 : 55 : 58 : 59 : 62 : 67 : 69$. It is yet premature to work out relationships for all the elements, for there is still great uncertainty about most of the atomic weights, but the values for most of the above substances are thoroughly well established.

MESSRS. HABER AND GEIPERT have been investigating the conditions under which aluminium is obtained by the electrolytic method, and have published their results in recent issues of the

Zeitschrift f. Elektrochemie. They point out that no trustworthy details of the method employed in the various works where the metal is now produced have hitherto been made public. Using a small experimental fusion cell, and the ordinary lighting supply current of the Karlsruhe Technical Institute, they were able to reduce alumina without difficulty and to obtain as much as 230 grams of the metal in one operation. The metal obtained was remarkably pure, one sample tested containing only ·05 per cent. C and ·034 per cent. Si. The mechanical tests made with six samples of the aluminium gave an average tensile strength of 21,425 lb. per square inch. The fused mixture used in the carbon cell contained 33 per cent. AlF_3, 33 per cent. NaF and 33 per cent. Al_2O_3, the high percentage of aluminium fluoride being conducive to fluidity. The current density employed was about 2800 amperes per square foot, and the E.M.F. varied between 7 and 10 volts. The authors, as the result of their experiments, have come to the conclusion that the steady improvement in the efficiency of the process as carried out in the aluminium works is due, not to secret modifications in the process, but to the more careful attention now given to the purity of the raw materials employed. They also point out that the carbon contained in the aluminium obtained in their experiments was not present in the combined form, and as it was graphitic in character they assume that it represented mechanically enclosed particles, due to the disintegration of the anode and kathode carbon. By remelting the aluminium, it was possible to remove a portion of this impurity from the metal. The necessity of employing carbons comparatively free from ash is insisted on, since any impurities of the carbon used will be found in the final product.

The additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. J. S. Sweetman; a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Colonel Ewart; a Tiger (*Felis tigris*) from India, presented by Mr. A. Forbes; two Two-spotted Paradoxures (*Nandinia binotata*) from West Africa, presented respectively by Major D'Arcy Anderson and Mr. Walter O'Brien; two Bank Voles (*Arvicola pratensis*) British, presented by Mr. G. T. Rope; a Broad-fronted Crocodile (*Osteoloemus tetraspis*) from West Africa, presented by Dr. W. F. Macfarlane; a White-collared Mangabey (*Cercocebus collaris*) from West Africa, a Black-faced Spider Monkey (*Ateles ater*) from Eastern Peru, a White-fronted Capuchin (*Cebus albifrons*) from South America, a Common Marmoset (*Hapale jacchus*), a Six-banded Armadillo (*Dasypus sexcinctus*) from Brazil, a Vulpine Phalanger (*Trichosurus vulpecula*) from Australia, two Petz's Conures (*Conurus canicularis*) from Mexico, a Western Boa (*Boa occidentalis*) from Argentina, deposited; five American Pochards (*Fuligula americana*) from North America, received in exchange.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN SEPTEMBER:—

Sept. 3. 7h. 59m. Minimum of Algol (β Persei).
6. 8h. 1m. to 11h. 43m. Transit of Jupiter's Sat. III.
13. 11h. 28m. to 15h. 11m. Transit of Jupiter's Sat. III.
15. Venus. Illuminated portion of disc = 0·945, of Mars = 0·948.
22. 9h. 2m. to 9h. 25m. Moon occults δ^1 Tauri (mag. 4·0).
22. 9h. 14m. to 10h. 2m. Moon occults δ^2 Tauri (mag. 4·7).
23. 8h. 13m. to 13h. 6m. Transit of Jupiter's Sat. IV.
23. 9h. 41m. Minimum of Algol (β Persei).
Sept. 23. 10h. 34m. to 11h. 12m. Moon occults 115 Tauri (mag. 5·4).
23. 12h. 0m. Sun enters Libra. Autumn commences.
23. 13h. 28m. to 13h. 53m. Moon occults 120 Tauri (mag. 5·3).
24. 17h. 0m. Mercury at greatest elongation (26° 11′ E.).
24. 17h. 32m. to 18h. 38m. Moon occults 26 Geminorum (mag. 5·1).
25. 13h. 40m. to 14h. 40m. Moon occults 68 Geminorum (mag. 5·0).
26. 6h. 30m. Minimum of Algol (β Persei).
27. 15h. 22m. to 15h. 38m. Moon occults ω Leonis (mag. 5·6).

NEW DISCOVERIES OF VARIABLE VELOCITIES IN LINE OF SIGHT.—In addition to the thirty-two binaries previously announced, Prof. Campbell records the data of six more spectroscopic binaries which have been detected with the Mills spectrograph; they are the following:—

φ *Persei*: $\alpha = 1h.\ 37m.$; $\delta = +50° 11'$. The maximum variation as yet recorded is from +24 km. (December 16, 1900) to −12 km. (November 11, 1901). This star has bright hydrogen lines, Hγ appearing as a narrow absorption line with very bright borders.

η *Geminorum*: $\alpha = 6h.\ 09m.$; $\delta = +22° 33'$. Maximum variation as yet recorded is from +14 km. (January 15, 1900) to 25 km. (February 2, 1902).

γ *Canis Minoris*: $\alpha = 7h.\ 23m.$; $\delta = +9° 08'$. Range of variability as yet detected is from +40 km. (November 6, 1901) to +54 km. (December 22, 1901).

ζ *Herculis*: $\alpha = 16h.\ 38m.$; $\delta = 31° 47'$. This is a well-known visual binary having a period of about thirty-three years, but the earlier observations of Belopolsky, Campbell and Newall in 1893, 1898 and 1897–99, respectively, did not establish the variability. However, by taking the means of these early observations and comparing them with the mean of the recently observed velocities determined at the Lick Observatory, it is found that the velocity has changed by about 4 km. since 1898.

α *Equuleі*: $\alpha = 21h.\ 11m.$; $\delta = +4° 50'$. The velocity of this star varied from −26 km. on June 25, 1900, to −2 km. on June 25, 1901, and then returned to −26 km. on June 2, 1902.

ο *Andromedae*: $\alpha = 22h.\ 57m.$; $\delta = +41° 47'$. The range of variability, so far as it is yet known, is from −11 km. (October 9, 1900) to −20 km. (June 25, 1901).

Miss Maury, of the Harvard College Observatory, has discovered the composite character of the spectra of the two last-mentioned stars.

Out of the 350 stars observed up to date, 41 have proved to be spectroscopic binaries, giving a proportion of one binary to every eight stars observed, not taking into account a number of suspected cases which await confirmation.

The variable velocity of the sun has a double amplitude of only a few hundredths of a kilometre, and Prof. Campbell suggests that, with increased accuracy in our methods of observation, we shall probably find that there is a regular gradation from this comparatively minute quantity up to the much greater velocities already recorded, and that it will be found that a star which is *not* a spectroscopic binary is a rare exception (Lick Observatory *Bulletin*, No. 20).

THE NAMING OF NEW VARIABLE STARS.—No. 3808 of the *Astronomische Nachrichten* contains a list of the titles which have been assigned to the 24 variables discovered during the years 1900, 1901 and 1902 by the commission appointed to this duty. Among the 24 there are only four variables of the Algol type, one of which has the remarkable period of 31·3 days.

The published table gives the star's number in Chandler's catalogue, its temporary name, the assigned permanent name, the maximum and minimum magnitudes, and the data regarding the position for 1900.

THE SPECTRUM OF NOVA PERSEI.—Prof. Campbell and Mr. Wright subscribe a short note to the Lick Observatory *Bulletin*, No. 20, on the later spectrum of Nova Persei (1901).

Spectrograms, obtained throughout the autumn and winter, up to January 7, 1902, showed no appreciable difference from the immediately preceding ones, the fine dark H (calcium) line referred to in *Bulletin* No. 8 still remaining visible. It was suggested that the corresponding K line did not appear because there was no light in that region of the spectrum for the calcium vapour to absorb, but this suggestion has been proved incorrect

by the appearance of the K line on a negative, obtained by Mr. Wright, which was given a very long exposure with the intention of deciding whether this line did, or did not, exist in the Nova spectrum.

The writers suggest that it would now be an exceedingly interesting experiment to test the presence of the absorption lines of calcium, sodium and other elements, in the gaseous nebulæ, by giving exposures long enough to record their continuous spectra.

THE CHANGES IN THE NEBULA SURROUNDING NOVA PERSEI.—Prof. Louis Bell, writing in the *Astrophysical Journal* (No. 1, vol. xvi.), discredits the "simple reflection" explanation of the changes which have taken place so rapidly in the nebulous matter surrounding the Nova, for the following reasons:—(1) Reflected light would be more or less polarised, and Perrine reports the total absence of polarisation in the light received from this nebula. (2) Reflection does not satisfactorily explain the persistence of strongly illuminated nebulosity at small angular distances from the Nova. (3) At the enormous distances (210 light days) from the Nova that some of the bright portions are situated, reflection would not account for the brightness of these parts.

Prof. Bell supports the theory of Seeliger, which accounts for the apparent movements of the brightest portions of the nebula, by supposing that the various parts of this highly tenuous matter are successively lighted up by the effects of a travelling electromagnetic wave-front, and shows that this theory agrees entirely with the observed phenomena.

HUGH MILLER: HIS WORK AND INFLUENCE.[1]

AMONG the picturesque figures that walked the streets of Edinburgh in the middle of last century, one that often caught the notice of the passer-by was that of a man of good height and broad shoulders, clad in a suit of rough tweed, with a shepherd's plaid across his chest and a stout stick in his hand. His shock of sandy-coloured hair escaped from under a soft felt hat; his blue eyes, either fixed on the ground or gazing dreamily ahead, seemed to take no heed of their surroundings. His rugged features wore an expression of earnest gravity, softening sometimes into a smile and often suffused with a look of wistful sadness, while the firmly compressed lips betokened strength and determination of character. The springy, elastic step with which he moved swiftly along the crowded pavement was that of the mountaineer rather than of the native of a populous city. A stranger would pause to look after him and to wonder what manner of man this could be. If such a visitor ventured to question one of the passing townsmen, he would be told promptly and with no little pride, "That is Hugh Miller." No further description or explanation would be deemed necessary, for the name had not only grown to be a household word in Edinburgh and over the whole of Scotland, but had now become familiar wherever the English language was spoken, even to the furthest western wilds of Canada and the United States.

A hundred years have passed since this notable man was born, and nearly half that interval has elapsed since he was laid in the grave. The hand of time, that resistlessly winnows the wheat from the chaff of human achievement, has been quietly shaping what will remain as the permanent sum of his work and influence. The temporary and transitory events in his career have already, in large measure, receded into the background. The minor contests in which, from his official position, he was so often forced to engage are mostly forgotten; the greater battles that he fought and won are remembered rather for their broad and brilliant results than for the crowded incidents that gave them such vivid interest at the time. His contemporaries who still survive him—every year a sadly diminishing number—can look back across the half century and mark how the active and strenuous nature whose memory they so fondly cherish, now

> "Orbs into the perfect star
> We saw not when we moved therein."

A juster estimate can doubtless be formed to-day of what we owe to him than was possible in his lifetime. That the debt is great admits of no dispute, and that it is acknowledged to be due could hardly be more fittingly shown than by the widespread desire which has brought us here to-day from so many distant places in order to raise in the town of his birth, which he made a place of pilgrimage to many a lover of English literature, a visible memorial of him in an institution of which he would himself have heartily approved.

In order adequately to realise the nature and extent of the work achieved by Hugh Miller during his too brief career, we should clearly picture to ourselves the peculiar conditions in which he grew up. Happily he has himself, in one of the most charming pieces of autobiography in the language, told the story of his youth and early manhood. Descended from both a Highland and a Lowland ancestry, he combined in his nature the vivid imagination and poetic impulse of the Celt with the more staid and logical temperament of the Teuton. He was born amidst an English-speaking community, but at a distance of only a few miles from the fringe of the mountainous region within which men use the Gaelic tongue. He knew some survivors of Culloden, and had heard his own grandfather tell how, when a stripling, he watched, from the hills above Cromarty, the smoke wreaths of the battle as they drifted along the ridge on the further side of the Moray Firth. From infancy he was personally familiar with the people of the hills and their traditions, as well as with the ways of the hardy fisher-folk and farmers of the plains. The hereditary predispositions of his mind were in this way fostered by contact with the two races from which they sprang.

Happy in the possession of this racial blending, he was still more fortunate in the place of his birth. He used to remark with satisfaction that both Sir Roderick Murchison and he had been born on the Old Red Sandstone of the Black Isle; but while the career of the author of the "Silurian System" owed practically nothing to his birthplace, which he left while still an infant, Miller's life from beginning to end bore the impress of the surroundings amid which he was born and educated. It would hardly be possible to choose in this country a place of which the varied features are more admirably fitted to stimulate the observing faculties, to foster a love of nature, and to appeal to the poetic imagination than the winding shores, the scarped cliffs, the tangled woods, the wild boulder-strewn moors and distant sweep of blue mountains around Cromarty. And how often and lovingly are these scenes portrayed by him under every varying phase of weather and season! They had stamped themselves into his very soul and had become an integral part of his being.

> "The sounding cataract
> Haunted him like a passion; the tall rock,
> The mountain, and the deep and gloomy wood,
> Their colours and their forms were then to him
> An appetite, a feeling, and a love."

But while Nature was his first and best teacher, he has told us in grateful words how much he owed to two uncles—hard-working, sagacious and observant men, by whom his young eyes were trained to discriminate flower and tree, bird and insect, together with the teeming organisms of the shore, and whose high moral worth he, even as a boy, could appreciate. Having learnt to read while still of tender years, he developed an insatiable thirst for books. What he acquired in this way for himself seems to have been at least as useful as the training gained during the rather desultory years spent by him at the town grammar-school. He was an intelligent but wayward boy, as much ahead of his schoolmates in general information as in all madcap adventures among the crags and woods. When the time arrived at which he had to choose his calling in life, he selected an occupation that would still enable him to spend his days in the open air and gratify his overmastering propensity for natural history pursuits. Much to the chagrin of his family he determined to be a stone-mason, and at the age of seventeen was apprenticed to that trade. For some fifteen years he continued to work in quarries and in the erection of buildings in various districts of the north country, and even extended his experience for a short time into Midlothian. Deeply interesting and instructive is the record he has left of these years of mechanical toil. But amidst all the hardships and temptations of the life, the purity and strength of his character bore him nobly through. His keen love of nature and his intense enjoyment of books were a never-failing solace. He continued to gain access to, and even by degrees to possess, a considerable body of the best literature in our language, reading some of his favourite authors over twice in a year. He thus laid up a

[1] An address given at the centenary celebration of the birth of Hugh Miller held in Cromarty on August 22, by Sir Archibald Geikie, D.C.L., F.R.S.

store of information and allusion which his retentive memory enabled him eventually to turn to excellent advantage.

While still at school he had gained some notice for the verses which he wrote. In the intervals of his subsequent labours with mallet and chisel, he continued to amuse himself in giving metrical expression to his feelings and reflections, grave or gay. Conscious of his power, though hardly yet aware in what direction it could best be used, he resolved to collect and publish his verses. At the age of seven-and-twenty he accordingly gave to the world a little volume with the title "Poems written in the leisure hours of a Journeyman Mason." Not without some misgiving, however, did he make this first literary venture. Even before the voices of the "chorus of indolent reviewers" could travel up from the south country, with their sententious judgments of the merits and defects of this new peasant-poet, he set himself to prepare some contributions in prose which might perchance afford a better measure of his quality. Some years before that time he had been out all night with the herring fleet, and he now sent to the *Inverness Courier* some letters descriptive of what he had then seen. These made so favourable an impression that they were soon afterwards reprinted separately. They marked the advent of a writer gifted with no ordinary powers of narration and with the command of a pure, nervous and masculine style. The reception which these letters met with from men in whose judgment and taste he had confidence formed a turning point in his career. He now realised that his true strength lay, not in the writing of verses, but in descriptive prose. Some years, however, still passed before he found the class of subjects on which his pen could most effectively be exercised. In the meantime he began to record the legends and traditions of his native district. Most of these had been familiar to him from childhood, when he heard them from the lips of old grey-headed men and women, but they were dying out of remembrance as the older generations passed away. Part of his leisure for several years was given to this pleasant task, until there grew up under his hand a bulky volume of manuscript. This time he was in no hurry to publish; the book did not make its appearance until 1835, as his charming "Scenes and Legends of the North of Scotland." In this work some of the most striking passages were to be found, not so much in the tales themselves which were narrated as in the local colouring and graphic setting that were given to them. The writer displayed a singularly vivid power in the delineation of scenery, and his allusions to the geology of the district, then almost wholly unknown, attracted attention, since they showed that besides his keen eye for the picturesque above ground, he knew something of the marvels that lay beneath. He was feeling his way to what ultimately became his most cherished and most useful task. He had realised that his main object should be to know what was not generally known, "to stand as an interpreter between nature and the public," and to perform the service of narrating, as pleasingly as he could, the facts which he culled in walks not previously trodden, and of describing, as graphically as might be, the inferences which he drew from them.

Ever after his first day's experience as an apprenticed mason in a stone-quarry, of which he has left more than one impressive account, he was led to interest himself in the diversified characters of the rocks of the district. Even as a boy he had been familiar with the more obvious varieties of stone to be met with in a tract of country wherein the sedimentary formations of the Lowlands and the crystalline masses of the Highlands have been thrown side by side. But he had been attracted to them rather on account of their singular shapes or brilliant colours than from any regard to what might have been their different modes of origin. Now, however, he had discovered that these rocks are really monuments, wherein are recorded portions of the past history of the earth, and he was full of hope that by patient study he might yet be able to decipher them. The supply of elementary treatises and text-books of science, in the present day so abundant, had hardly at that time begun to come into existence. Geology, indeed, had but recently attained a recognised position as a distinct branch of science. And even had the young stone-mason been able to possess himself of the whole of the scanty geological literature of the time, it included no book that would have solved for him the problems that daily confronted him as he pursued his labours in the quarry, or rambled in leisure hours along the shore. The best treatise which could have fallen into his hands and which would have been full of enlightenment and suggestion for him—Playfair's immortal "Illustrations of the Huttonian Theory"—had appeared seventeen years before; but we have no evidence that it came in his way. He had laboriously to work out his problems for himself.

Innumerable as are the subjects for geological inquiry offered by the district of Cromarty, it was fortunate for Hugh Miller, and not less so for the cause of science, that chance placed him face to face in the most practical way with the Old Red Sandstone, and that he was, as it were, compelled to attempt to understand its history. While the lessons taught by the strata of the quarry had greatly impressed him, the abundant and well-preserved fossils among the Lias shales of the Eathie shore, which at spare moments he visited, had deepened that impression. It was while endeavouring to find these shales nearer home, on the western side of the Southern Sutor, that he stumbled upon the clays which contain the fish-bearing nodules of the Old Red Sandstone. This happy discovery, which was made in the autumn of 1830, the year after the publication of his "Poems," marks an eventful epoch in his life, as well as an important date in the history of geological investigation.

At that time comparatively little was known of the Old Red Sandstone. Its very existence as a distinct geological system was disputed on the continent, where no equivalent for it had been recognised. It was alleged to be a mere local and accidental accumulation, which could hardly be considered as of much historical importance, seeing that no representative of it had been found beyond the British Islands. Yet within the limits of these islands it was certainly known to bulk in no inconsiderable dimensions, covering many hundreds of square miles and attaining a thickness of more than 10,000 feet. It had been clearly shown by William Smith, the father of English geology, to occupy a definite position beneath the Mountain Limestone and above the ancient "greywacke" which lay at the base of all the sedimentary series, and he had indicated its range over England and Wales on his map published as far back as 1815. In Scotland, too, its existence and importance as a mere mass of rock in the general framework of the country had long been recognised. Ami Boué had published in 1820 an excellent account of its igneous rocks, but without any allusion to the organic wonders for which it was yet to become famous. The extraordinary abundance of its fossil fishes, where it spreads over Caithness, had been made known to the world by Murchison in 1826, and in more detail the following year, when Sedgwick and he read their conjoint paper on the conglomerates and other formations of the north of Scotland. But it may be doubted if any of these publications had found their way to Cromarty when Miller was gathering his first harvest of ichthyolites in the little bay within half a mile of the town. He had passed over that beach many hundreds of times in his boyhood without a suspicion of the treasures wrapped up in the grey concretions that lay tossing in the tideway. On breaking these stones, hoping to meet with a repetition of the Liassic organisms with which he had grown familar at Eathie, he found a group of forms wholly different. At each interval of leisure he would repair to the spot, and, digging out the nodules from their matrix of clay, would patiently split them open and arrange them along the higher part of the beach, according to what seemed to be the natural affinities of the fossils enclosed within them. Scouring the parish for fresh exposures of the nodule-bearing clay, he was soon rewarded by the discovery of some six or eight additional deposits charged with the same remains. There was a strange fascination in this pursuit. He had, as it were, discovered a new world. No human eye had ever before beheld such strange types of creation. Though he was well acquainted with the marine life of the adjacent firths, he had never seen any creature that in the least resembled them, or served to throw light on their structure.

With no chart or landmark to guide him into this new domain of nature, he continued for years quietly to collect and compare. The first imperfect knowledge which he was able to acquire regarding the few modern representatives of the creatures disinterred by him at Cromarty was derived in 1836 from a perusal of the well-known memoir by Hibbert on the limestone of Burdiehouse. Next year, however, he made the acquaintance of Dr. Malcolmson, who eventually carried some of his specimens to London and the continent, and was the means of bringing him into correspondence with Murchison and Agassiz. Hugh Miller was thus at last placed in direct communication with the world of science and into relation with the men who were most thoroughly versed in the subjects that had

so long engrossed his thoughts, and most capable of helping him to clear away the difficulties that beset his progress.

Meanwhile an important change had taken place in his condition of life. During the year 1834, after having worked for fifteen years in his calling of stone-mason, he was offered the accountantship of the Commercial Bank agency to be opened at Cromarty. This offer, which came to him unasked and unexpected, was a gratifying mark of the esteem and confidence with which his character was regarded. He accepted it, not without some diffidence as to his competence for the duties required. It would, however, retain him in his native town, enable him to marry the accomplished girl to whom he had for years been attached, and afford him opportunity to prosecute the researches in the Old Red Sandstone, of which he had now come to realise the importance. It likewise provided him with leisure to prepare contributions to different periodicals, which, though of no great consequence to his reputation, were of service in adding to an income narrow enough for the support of a wife and family. These writings had this further advantage, that they gave him a readier command of the pen and accustomed him to deal with lighter as well as with graver subjects of discussion, thus furnishing a useful training for what was ultimately to be the main business of his later life.

At this time ecclesiastical questions occupied public attention in Scotland to the exclusion of almost everything else. The Church was entering on that stormy period which culminated in the great Disruption of 1843. Hugh Miller, who was at once an earnest Christian and a devoted son of the Church, watched the march of events with the deepest sympathy. As a thoroughly "Establishment man" he had taken but slender interest in the previous Voluntary controversy, but the larger and more vital conflict now in progress filled him with concern. It was his firm conviction that the country contained "no other institution half so valuable as the Church, or in which the people had so large a stake." The anxiety with which the situation impressed him affected his sleep, and he would ask himself, "Can I do nothing for my Church in her hour of peril?" The answer which he found was to write his famous "Letter from one of the Scotch people to Lord Brougham." This pamphlet was soon after followed by another, entitled "The Whiggism of the Old School, as exemplified in the past history and present position of the Church of Scotland." These writings, so cogent in argument and so vigorous in style, had a wide circulation, and undoubtedly exercised much influence on the progress of the ecclesiastical controversy throughout the country. The leaders of the non-intrusion party, with whose cause he showed such keen and helpful sympathy, soon after the appearance of the first pamphlet invited Miller to confer with them in Edinburgh, and offered him the editorship of their projected newspaper, the *Witness*. With some misgiving as to his competence to meet all the various demands of a journal that was to appear twice a week, he accepted the proposal. Thus, after his five years' experience as a bank-accountant, he became at the beginning of 1840, when he was thirty-seven years of age, the editor of an important newspaper, and he retained that position until his death.

Up to this time the name of Hugh Miller was but little known beyond his native district. His political pamphlets first gave it a wide reputation, and thenceforth his conduct of a journal that represented the interests of one of the great parties into which his country was divided kept him constantly before the eyes of the public. The *Witness* rapidly attained a large circulation. It appealed, not merely to the churchmen whose views it advocated, but to a wide class of readers, who, apart from ecclesiastical polemics, could appreciate its high tone, its sturdy independence, its honesty and candour, and the unusual literary excellence of its leading articles. It not only upheld, but raised the standard of journalism in Scotland. As a great moral force it exercised a healthy influence on the community. There cannot be any doubt that the powerful advocacy of the *Witness* was one of the main agencies in sustaining the energies of the non-intrusion party and in consolidating the position of the young Free Church. It is my own deep conviction that the debt which that Church owes to Hugh Miller has never yet been adequately acknowledged.

Before he had been many months in the editorial chair he began to publish in the columns of his paper the first of that brilliant succession of geological articles which attracted the attention of men of science, as well as of the general public, and which continued to be a characteristic feature of the *Witness* up to the end of his life. The first articles, describing his discoveries in the Old Red Sandstone of Cromarty, created not a little sensation among the geologists who had gathered in the year 1840 at the memorable meeting of the British Association at Glasgow. It was there that Agassiz, who had come fresh from the study of Swiss glaciers to the Scottish Highlands, announced that he had found clear evidence that the mountains of this country had once also nourished their glaciers and snowfields. It was then, too, that the same illustrious naturalist gave the first account of the fossils found by Hugh Miller at Cromarty, one of which he named after its discoverer. In that gathering of eminent men, Murchison declared that the articles which had been appearing in the *Witness* were "written in a style so beautiful and poetical as to throw plain geologists like himself into the shade." Buckland, famous for his own eloquent pages in the Bridgewater Treatise, expressed his unbounded astonishment and admiration, affirming that "he would give his left hand to possess such powers of description." The articles were next year collected and expanded into his "Old Red Sandstone, or New Walks in an Old Field"—the first and, in some respects, the freshest and most delightful of all his scientific volumes.

In subsequent years there appeared in the same columns his "Cruise of the Betsy"—a series of papers written among the Western Isles, and full of the poetry and geological charm of that marvellous region; his "Rambles of a Geologist," in which he included the results of his wanderings over Scotland between 1840 and 1848, and other essays, the more important of which were collected with pious care by his widow and published in a succession of volumes after his death. His "First Impressions of England and its People" appeared in 1846, and greatly increased the reputation of its writer as an observant traveller, an able critic and an accomplished writer, possessing a wide and sympathetic acquaintance with English literature. The "Footprints of the Creator," which followed in 1847, was of a less popular character. Its detailed account of the structure of some of the fishes of the Old Red Sandstone is, however, of lasting value, though its controversy with the "Vestiges of Creation" has now little more than an historical interest. The "Schools and Schoolmasters," after running as usual through the pages of the newspaper, was issued as a separate volume in 1852, and was everywhere hailed as one of the most delightful and instructive of all his works. The "Testimony of the Rocks," with the final proofs of which he was engaged on the last day of his life, was issued a few months after he had been laid to rest beside his friend Chalmers. Altogether of his collected writings, including those that appeared in his lifetime, a series of twelve volumes has been published, but many hundreds of articles of less permanent interest, yet each marked by the distinctive charm of its writer, remain buried in the files of the *Witness*.

If, from his writings alone, we judge of the extent and value of the work achieved by Hugh Miller, we can have little hesitation in believing that it is mainly his contributions to the literature of science that will hand his name down to future generations. Like so many other men who have attained distinction in the same field, he from the beginning to the end made geology his recreation, in the midst of other paramount preoccupations. It furnished him with solace from the toils of the quarry and the building yard, it supplied him with a healthful relief from the labours of the bank, and when in later years he escaped each autumn for a few weeks of much-needed leisure from the cares and responsibilities of the editor's desk, it led him to ramble at will all over his native country, and brought him into acquaintance with every type of its rocks and its landscapes.

Unquestionably the most original part of his scientific work, that wherein he added most to the sum of acquired knowledge, is to be found in his reconstruction of the extinct types of fishes which he discovered in the Old Red Sandstone. The merit of these labours can hardly be properly appreciated unless it be borne in mind that he came to the study of the subject with no preliminary biological training save what he could pick up for himself from an examination of such denizens of the neighbouring firths as he could meet with. But after prolonged search he could find in these northern seas no living creatures the structure of which afforded him any clue to that of the fossil fishes of Cromarty. Some men had concluded that the organisms were ancient turtles, others that they were crustaceans or even aquatic beetles. He had the sagacity, however, to surmise that they were probably all fishes, and he

enjoyed the satisfaction afterwards of learning that Agassiz pronounced even the most bizarre amongst them to belong to that great division of the animal kingdom. He was guided by his own intuitive conception of what must have been the plan on which these long-vanished types of organic structure had been fashioned. Huxley, who twenty years afterwards had occasion to subject the Old Red Sandstone fishes to critical study, and who brought to the inquiry all the resources of modern biology, has left on record the impression made on his mind by a minute revision of Hugh Miller's work. "The more I study the fishes of the 'Old Red,'" he remarks, "the more am I struck with the patience and sagacity manifested in Hugh Miller's researches, and by the natural insight which in his case seems to have supplied the place of special anatomical knowledge." He refers to the "excellent restoration of Osteolepis," in which even some of the minute peculiarities had not escaped notice, and he declares that Hugh Miller had made known almost the whole organisation of Dipterus, and had thus anticipated the most important part of Prof. Pander's labours in the same field, the distinguished Russian palæontologist not having been aware that the work had already been done in Scotland.

But it is not, in my opinion, by the extent or value of his original contributions to geology that the importance of Hugh Miller's scientific labours and writings should be measured. Other men, who have left no conspicuous mark on their time, have surpassed him in these respects. What we more especially owe to him is the awakening of a widespread interest in the methods and results of scientific inquiry. More than any other author of his day, he taught men to recognise that beneath the technicalities and jargon that are too apt to conceal the meaning of the facts and inferences which they express, there lie the most vital truths in regard to the world in which we live. He clothed the dry bones of science with living flesh and blood. He made the aspects of past ages to stand out once more before us, as his vivid imagination conceived that they must once have been. He awakened an enthusiasm for geological questions such as had never before existed, and this wave of popular appreciation which he set in motion has never since ceased to pulsate throughout the English-speaking population of the world. His genial ardour and irresistible eloquence swept away the last remnants of the barrier of orthodox prejudice against geology in this country. The present generation can hardly realise the former strength of that bigotry, or appreciate the merit of the service rendered in the breaking of it down. The well-known satirical criticism of the poet Cowper expressed a prevalent feeling among the orthodox of his day, and this feeling was still far from extinct when Miller began to write. I can recall manifestations of it even within my own experience. No one, however, could doubt his absolute orthodoxy, and when the cause of the science was so vigorously espoused by him, the voices of the objectors were finally silenced. There was another class of cavillers who looked on geology as a mere collecting of minerals, a kind of laborious trifling concealed under a cover of uncouth technical terms. Their view was well expressed by Wordsworth when he singled out for contemptuous scorn the enthusiast

> "Who with pocket hammer smites the edge
> Of luckless rock or prominent stone,
> Detaching by the stroke
> A chip or splinter, to resolve his doubts,
> And, with that ready answer satisfied,
> The substance classes by some barbarous name
> And hurries on ;
> He thinks himself enriched,
> Wealthier, and doubtless wiser, than before."

But a champion had now arisen who, as far as might be, discarding technicalities, made even the dullest reader feel that the geologist is the historian of the earth, that he deals with a series of chronicles as real and as decipherable as those that record human events, and that they can be made, not only intelligible, but attractive, as the subjects of simple and eloquent prose.

The absence of technical detail, which makes one of the charms of Hugh Miller's books to the non-scientific reader, may be regarded as a defect by the strict and formal geologist. Like every other branch of science, geology rests on a basis of observation, which frequently depends for its value upon the minuteness and accuracy of its details. To collect these details is often a laborious task, which is seldom undertaken save by those to whose department of the science they specially belong. A palæontologist cannot be expected to devote his time to the study of the microscopic characters of minerals and rocks. He leaves that research to the petrographer, who, on the other hand, will not readily embark on an investigation of the minute anatomy of fossil plants or animals. This specialisation, which has always to some extent existed, necessarily becomes more pronounced as science advances. The days are far past for Admirable Crichtons, and it is no longer possible for any one man to be equally versed in every branch of even a single department of natural knowledge.

Hugh Miller's researches among the Old Red Sandstone fishes showed him to be above all a naturalist and palæontologist, capable of expending any needful amount of patient labour in working out the minutest details of organic structure. In other fields of geological inquiry, while he was far from undervaluing the importance of detail, he avoided the recapitulation of it in his writings. It interested him, indeed, only in so far as it enabled him to reach some broad conclusion or to fill in the canvas of some striking picture of bygone aspects of the earth's surface. Hence he did not apply himself to the minute investigation of problems of geological structure, and when he undertook any inquiry in that direction he was apt to start rather from the palæontological than the physical side. Thus the work of his last years along the shores of the Firth of Forth, wherein he sought to accumulate proofs of the comparatively recent upheaval of the land, was mainly based on the position of shells with reference to their present habitat in the adjacent seas. As a youth enthusiastically geological, I was privileged to enjoy his friendship, sometimes accompanying him on an excursion, and always spending an evening with him after one of his autumn journeys that we might exchange the results of our several peregrinations. Only a week or two before his death, on the last of those memorable evenings, he had his trophy of shells spread on the table, which enabled him to prove that at no very distant date Scotland was cut in two by a sea-strait that connected the Firths of Forth and Clyde. He had found marine shells at Bucklyvie, on the flat ground about midway between the two estuaries. Finding I was not quite clear as to the precise geographical position of his shell-bed, he burst out triumphantly with the lines placed by Scott at the head of the chapter in "Rob Roy," which tells of the journey of Bailie Nicol Jarvie and Osbaldistone into the Highlands :

> "Baron of Bucklyvie
> May the foul fiend drive ye,
> And a' to pieces rive ye,
> For building sic a toun,
> Where there's neither horse meat, nor man's meat, nor a chair to sit doun."

I remember, too, that on that occasion I had brought with me the detailed map of Arthur's Seat at Edinburgh, of which I had just completed the geological survey, and I explained to him in some detail what I had found to be the structure of the hill. Having grasped the main succession of the rocks, he with characteristic rapidity passed from the particulars which I had given him to the events of which they were the record, and turning to his daughter, who was sitting near, he exclaimed to her, "There, Harriet, is material for such an essay as has been prescribed to you at school." Then in a few graphic sentences he drew a picture of what seemed to him to have been the history of the old volcano.

While various causes no doubt contributed in this country to the remarkable and rapid increase in the general appreciation of the interest of geological investigation, I feel assured that one of the chief of them has been Hugh Miller's imaginative grasp of the subject and his eloquent advocacy. The personal experience of a single individual can count for little in an estimate of this kind ; but for what it may be worth, I gladly avail myself of this opportunity to state mine. It was Hugh Miller's "Old Red Sandstone" that first revealed to me the ancient history that might be concealed in the hills around me, and the meanings that might be hidden in the commonest stones beneath my feet. I had been interested in such objects, as boys are apt to be who spend much of their time in the open country. But it was that book which set me on the path of intelligent inquiry. And this experience must doubtless have been shared by many thousands of his readers who never saw his living face and who never became geologists.

I have alluded to the excellence of his literary style—a characteristic which, unfortunately, is only too rare among writers in science. There can be little doubt that this feature of his work will constitute one of its claims to perpetual recognition. His early and wide acquaintance with our literature enabled him to intersperse through his pages many an apposite quotation and

felicitous allusion. He had set before himself as models the best prose writers of the previous century, and the influence of Goldsmith upon him is especially notable. He thus acquired the command of pure, idiomatic and forcible language wherein to clothe the arguments which he wished to enforce, to describe the landscapes which had imprinted themselves like photographs on his memory, and to present restorations of ancient lands and seas which his poetic temperament and powerful imagination called up before his eyes. Moreover, he had a keen sense of humour, which would show itself from time to time, even in the midst of a scientific discussion. He could not bear dulness in others, and strove to avoid it himself. Where his subject might have been apt to grow wearisome, he contrived to lighten it with unexpected flashes of pleasantry or with some pertinent words from a favourite author. This felicitous style seemed so spontaneous, and yet it was in reality the result of the most scrupulous attention. Even in his newspaper articles on the multifarious topics of the passing day, he continued to maintain the same high standard of composition. He has left as his literary monument a series of works that may serve as models of English writing.

In estimating a man's influence on the world we look, not only at his work, but on his character, often the more important and valuable of the two. Judged from this side, Hugh Miller's claims to our regard and admiration are not less strong for what he was than for what he did. Pious and pure-minded, full of generous sympathies, and alive to all that was noblest and best in human life, he was endowed with a manly independence of nature which kept his head erect in every changing phase of his career, and won for him the respect of all, gentle and simple, who came in contact with him. Though naturally robust, his occupation as a mason had left behind some seeds of disease. He was at different times attacked with inflammation of the lungs and other disorders of enfeebled health. His strong sense of duty, however, kept him at his post when prudence earnestly counselled rest. At last the strain became too great, and brought a noble and well-spent life to a sudden and tragic end.

It is to me a valued privilege to take part to-day in the centenary celebration of such a man. The years slip away, and I am probably the only geologist now alive who knew Hugh Miller well. He was my earliest scientific friend. Some boyish articles I had written in an Edinburgh newspaper on a geological excursion to the Isle of Arran had gained me his acquaintance, and ever thereafter I enjoyed his friendship and profited by his encouragement. To his helpful intervention I owed my introduction to Murchison, and thence my entry into the Geological Survey. His death was one of the great bereavements of my youth. It is therefore with heartfelt gratification that here, in his native town, so early familiar to me from his graphic descriptions, I find myself permitted on this public occasion gratefully to express my life-long indebtedness to him for his noble example, for the stimulus of his writings, and for the personal kindness which I received at his hands.

WHAT THE UNITED STATES OF AMERICA IS DOING FOR ANTHROPOLOGY.[1]

HAVING recently had the good fortune to pay a somewhat extended visit to the United States of America, I have thought it might not be uninteresting to you to hear what our kinsmen and colleagues across the Atlantic are doing for the furtherance of anthropology.

The means for the advancement of the science of anthropology fall under the following heads :—(1) The collection of information in the field ; (2) the publication of such information ; (3) the collection of specimens ; (4) the preservation of specimens ; (5) the publication of museum specimens ; (6) the instruction of students ; (7) independent investigation of collected material.

As no hard and fast line can be drawn between some of these activities, I shall deal first with the museums and with the field work undertaken by the more important institutions in the United States of America, and then very briefly with the teaching of anthropology in the United States.

[1] Abridged from the presidential address delivered by Dr. A. C. Haddon, F.R.S., before the Anthropological Institute on January 28. The address is published in full in the current number of the *Journal* of the Institute.

I. *Field Work and Museums.*

It is a glory to the nation of the United States that it has recognised the duty of collecting information about the aboriginal Americans. The twenty or more annual reports published by the Bureau of Ethnology constitute a monument to the intelligence of the Government and of its departmental officials of which their country may well feel proud. Nor does the Bureau of Ethnology neglect the collection of specimens, as is evidenced by the very extensive collections transferred to the National Museum. I cannot, however, refrain from remarking that it seems very strange that the anthropography, or physical anthropology, of the native tribes is entirely neglected by the Bureau, and I know that others share with me the hope that this state of affairs will be remedied.

The head curator of the department of anthropology in the National Museum, Dr. W. H. Holmes, is gradually working out his conception of what his museum should be. His object is twofold : (1) to illustrate the cultural history of mankind; (2) to demonstrate the distinctive characteristics of the various races and people.

(1) Numerous series of objects have been installed to illustrate the progress of culture, such, for example, as the various stages of evolution from stone implements, on the one hand, to the most modern steel tools and engineering appliances on the other. In this work the curator has been ably helped by the veteran Dr. Otis T. Mason, whose writings on technology are so well appreciated by students. An admirable land transport series has been got together, and one hall is devoted to a wonderful collection illustrating transport by water. There is also an interesting section devoted to comparative religions, of which Dr. Cyrus Adler is the custodian. No Government in the world does so much for ethnology as does that of the United States.

The Free Museum of Science and Art in Philadelphia contains some very valuable and pleasingly arranged collections of Babylonian, Egyptian and Etruscan antiquities. Good representative collections of American ethnology and archæology are being got together, owing to the exertions of Mr. Culin, the director. Of the special collections given to the university, mention need be made only of the collection of gems, of musical instruments and the Furness-Hose collection from Sarawak. In the museum is also to be found Mr. Culin's very instructive and almost exhaustive collection of games, but unfortunately it is stored away in drawers. If this collection was adequately exhibited it would give to the museum a unique position among anthropological museums.

It is instructive to note that although this is a university museum, no support is received from the university, all the scientific work being prosecuted by funds raised from private sources, a result largely due to the enthusiasm of Dr. Sara Y. Stevenson, the energetic secretary of the department.

In 1869 a little band of public-spirited men was created by the Legislature "a body corporate by the name of 'the American Museum of Natural History,' to be located in the city of New York, for the purpose of establishing and maintaining in said city, a Museum and Library of Natural History ; of encouraging and developing the study of Natural Science ; of advancing the general knowledge of kindred subjects, and to that end of furnishing popular instruction and recreation."

A partnership, under sanction of the law, was entered into by the citizens of New York in their corporate capacity with the president and trustees of the museum, it being mutually agreed that the city should pay for the erection of the buildings, their maintenance and protection, while the trustees took upon themselves the responsibility of providing the exhibits, the library, the lectures and other means of instruction and mental recreation. This arrangement is perpetual and irrevocably binding on both parties.

The anthropological department of the museum has accomplished an unprecedented amount of research during the past year, a large sum of money having been received from private sources for the purchase of several important collections of American archæology and ethnology and for the expenses of many expeditions in the field.

The greater part of the anthropological collections in the Yale University Museum are archæological in character. The Peabody Museum of Harvard University is already overcrowded and fresh collections are constantly arriving, which the curator, Prof. F. W. Putnam, is forced to keep in boxes in the store rooms. The main collections are the results of the

digging of mounds in the Eastern and Central States; thus the archæology of that portion of America can be very well studied in the museum. During the years 1887 to 1893 the late Mrs. Mary Hemenway provided funds for archæological and ethnological expeditions to the Pueblo Indians of Arizona and New Mexico.

The history of the progress of anthropology in Chicago is eminently characteristic of that typical American city.

There is no need to give a detailed history of the anthropological department of this museum, as Dr. Dorsey has already done so in the *American Anthropologist*, n.s., ii. 1890, p. 247; but I will briefly indicate the main collections and their origin.

The anthropological collections which formed the foundation of the department were obtained through special expeditions sent out under the direction of Prof. F. W. Putnam, or by collectors resident in the field, who were commissioned by the department of ethnology to undertake the work. A mass of interesting and valuable material from Alaska to Peru was thus accumulated. A few collections from other quarters of the globe were also obtained. The history of the museum since then has been one of almost unparalleled activity. Expedition after expedition has been sent out to collect ethnological and archæological material in North and Central America; some of these have been paid for out of the museum funds, while others have been rendered possible by special donations from benefactors, most of whom are Chicago merchants.

The more technical aspect of the museum has been so well described by Dr. A. B. Meyer that I need not dwell upon it.

The most recent inauguration of anthropological activity is that displayed by the University of California. A department of anthropology was established by the Regents of the University in September, 1901.

As an encouragement to others and as an expression of her great interest in the new department, Mrs. Phœbe A. Hearst, who is one of the Regents and a most generous benefactor to the University, has promised 10,000*l*. (50,000 dollars) a year for five years for anthropological research. In this manner is struck the key-note of the new department. Research first and foremost. We may look forward in the immediate future to the establishment of a really important museum on the Pacific coast which, being under the jurisdiction of the University of California, will be the centre of considerable anthropological research and instruction.

Now that the financial position of the Stanford University at Palo Alto is permanently secured, it is to be hoped that the claims of anthropology will not be overlooked.

This is not the place to describe the points of interest in the various museum buildings, the installation of the collections and the details relating to museum administration and technique. It is the less necessary as Dr. A. B. Meyer, of Dresden, who is a recognised authority on all matters pertaining to museums, travelled in the United States in 1899, and he is publishing a series of well-illustrated reports on the institutions he visited. These reports are invaluable to all those who are interested in the promotion or maintenance of museums and libraries, and it is to be hoped that no architect in the future will attempt to draw up plans for a new museum or library until he has consulted this work.[1]

II. *The Teaching of Anthropology in the United States of America.*

In America courses of anthropology were established about fifteen years ago at Harvard University and at the University of Pennsylvania. It was one of the first subjects introduced into the curriculum of the University of Chicago. Seven or eight years ago anthropology was recognised in Columbia University in the city of New York. At the present time some thirty-three universities and colleges offer instruction in anthropology. Limit of space precludes my giving details concerning the instruction in anthropology in these numerous institutions, so I confine myself to a consideration of two of the universities where the teaching is most firmly established. Further information on this subject will be found in Prof. G. G. MacCurdy's report on "The Teaching of Anthropology in the United States" in *Science*, n.s., vol. xv. 1902, p. 211.

It would be impossible to include within the limits of a brief address an account of all the work that is being done in anthropology by the Government, by public and private institutions, or by individual effort in the United States of America. Much as I should have liked to have emphasised the interest exhibited in the subject and the wonderful activity that is being displayed, the bare enumeration of all this activity would make a very weary chronicle.

I must confess that I felt a not inconsiderable amount of envy when on every hand I witnessed this energy and then recalled the apathy which pervades our own country.

The American public is more intelligently alive to the interest and importance of anthropology than is our public. The exponents of the science are energetic, enthusiastic and competent, and they succeed in gaining the practical sympathy of wealthy merchants, who are not averse to spending money freely when they see that the money will be wisely spent for the good of the State or of the city. One cannot say that the wealthy Americans are more intelligent than are our rich men, but they do seem to appreciate the value of learning to a much greater extent than do ours. At all events, they respond more readily to the very pressing need there is for the endowment of research and of those institutions which bring the knowledge of the expert down to the comprehension of the masses.

I am quite willing to admit that the fault in this country may lie as much with the specialist as with the capitalist. In any case we have an inspiriting demonstration in the United States of America of what can and should be done in Great and Greater Britain, and I venture to thank our American colleagues in the name of anthropological science for this good example of strenuous effort and praiseworthy accomplishment.

[1] The two parts already issued are entitled "Ueber Museen des Ostens der Vereinigten Staatne von Nord Amerika." Reisenstudien von A. B. Meyer. (Berlin: R. Friedländer und Sohn.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE new municipal school of technology in Manchester will be opened by Mr. Balfour on October 15.

DR. W. PALMER WYNNE, F.R.S., professor of chemistry in the School of Pharmacy of the Pharmaceutical Society, will deliver an address at the inauguration of the sixty-first session of the School on October 1.

MR. PARKIN, who has just gone to America to formulate a plan for putting into execution the provisions of Mr. Cecil Rhodes's will, has, a correspondent of the *Times* reports, been trying to interest Mr. Pierpont Morgan in a plan whereby the Rhodes scholarship scheme should be made reciprocal, the same number of young Englishmen being educated at American universities as Americans at Oxford. When he landed at New York on August 20, Mr. Parkin said:—"I think it would be a most splendid thing for some liberal American, or several Americans, to endow in some of your great colleges scholarships for the benefit of English youths similar to those founded by the bequest of Mr. Rhodes for the young men of America at Oxford." The same idea was put forward in several American papers when the terms of Mr. Rhodes's will were announced.

THE Childhood Society was founded some five years ago by the late Sir Douglas Galton, and, as its fifth annual report shows, it continues to grow in importance and usefulness. The objects of the Society are to promote the study of educational methods and of the environment of children during school life, with a view to discover the conditions best suited to ensure the healthy mental and physical development of normal children, and those best adapted to the peculiar needs of the mentally feeble and otherwise abnormal children. For the first time, the council of the Society has printed and issued the lectures and papers delivered at its meetings in book form, under the title of "Volume I. of the Transactions of the Childhood Society." A glance through the list of the Society's officers for the current year reveals a desirable cooperation between medical men and professional educationists which cannot fail to result in an improvement in the structure and equipment of schools as well as in the less material conditions of the class room.

A RECENT return printed by the order of the House of Commons, tabulating the sums applied by local authorities to the purposes of technical education, shows that the total amount expended on technical education in England and Wales during 1900–1 was 1,051,422*l*., but this does not include sums allocated to intermediate and technical education under the Welsh Intermediate Education Act. The total amount of

money available under the Local Taxation (Customs and Excise) Act for technical education in England (excluding Monmouthshire), or, as the grant is usually called, the "whisky" money, was during the same period 924,360*l.*, but only a part was appropriated to educational purposes, 60,513*l.* going to the relief of rates, the London County Council recognising this unenlightened policy to the extent of 32,711*l.* It is gratifying to find, however, that nine only of the forty-nine county councils included in the return devote part of their funds available for education to the relief of rates, and only six of the sixty-two county borough councils allow any such diversion of funds. More than this, two county councils, twenty-four county borough councils, ninety-nine boroughs and 195 urban districts are making grants out of the rates under the Technical Instruction Acts. In Wales and Monmouth, the whole of the "whisky" money is devoted to education, and in addition to this sum about 24,000*l.* raised by rates was expended for the same purpose during the period under review.

ON August 23, Prof. Geddes presided over the Nature-Study Conference organised in connection with the University Extension Meeting at Cambridge, and Mr. Wilfred Mark Webb gave an address on his "Impressions of 'Nature-Study.'" Mr. Webb showed the importance of the three branches of nature-study which he recognises with reference to four of its non-utilitarian aims. "Scientific teaching will often provide," he said, "a definite hobby or interest in life." Going to the other extreme, simple "nature-lore"—studied out of doors—may be expected to add to "the mere joy of existence," to produce "an appreciation of the country and its pursuits," and in correlation with "unsystematised nature-knowledge"—acquired in school as part of general education—to cultivate "habits of investigation by directing natural curiosity into rational channels." The necessity of emphasising outdoor work, the ease with which it may be undertaken off-hand by any teacher and the possibility of regarding it as nature-study in a restricted sense were touched upon. Mr. Macan's excellent suggestion that special nature-study training colleges should be inaugurated by groups of county councils was strongly commended. In the interesting discussion which followed, Miss Ravenhill showed how nature-study leads to the necessary consideration of man in his environment. Prof. Haddon hinted that the best naturalists, and therefore teachers of nature-study, were not necessarily those who had passed examinations. Mr. Oldham disagreed with those who would confine nature-study to animate objects and thus exclude the consideration of the earth itself. Miss Von Wyss described the voluntary biological work undertaken by all the students in the Cambridge Training College.

SCIENTIFIC SERIAL.

Journal of Botany, August.—Continuing their descriptions of "Crassulas from South Africa," Mr. S. Schönland and Mr. E. G. Baker introduce twelve new species of the genus.—A bryological article, with illustrative plate, by Mr. E. S. Salmon is mainly concerned with a consideration of the genus Thiemea, C. Müll, which he is inclined to sink in the genus Wilsoniella of the same authority, and the description of a variety of *Syrrhopodon Gardneri*, Schwaegr.—Other articles are:—Buchanan's Avan Plants, J. Britten; *Hieracium murorum* and *H. caesium*, F. N. Williams; West Lancashire Notes, C. E. Salmon and H. S. Thompson.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 18.—M. Bouquet de la Grye in the chair.—The resistance to traction of mortar, by M. Considère. The experiments were carried out on prisms strengthened at the angles with iron wires. The results of the traction experiments were automatically recorded by the testing machine, and reduced facsimiles of these curves accompany the paper.—On the year's work at the observatory at the summit of Mont Blanc, by M. J. Janssen. The researches which are proposed for the present year include a study of the modifications which the hæmoglobin of the blood undergoes with muscular effort at varying altitudes, the relations between the altitude and rarity of the atmosphere, and the richness of the spectrum in violet and ultra-violet rays, studies on atmospheric electricity, and the effect upon the composition of the blood and the respiratory exchanges of altitude alone or combined with muscular effort.—On the assemblage of two bodies, by M. G. Kœnigs.—On some organic addition compounds, by M. P. Lemoult. A description of the preparation and properties of some addition compounds of chlorodinitrobenzene with some diamines.—Experimental researches on the conservation of muscular potential in an atmosphere of carbon dioxide, by M. Lhotak de Lhota. Carbonic anhydride accelerates the fatigue of a muscle by stopping the disengagement of energy. On account of this the muscle cannot be used up; the energy may be given off after the removal of the carbon dioxide, and hence this gas constitutes a favourable factor in preserving muscular energy.—The comparative study of the organic fluids of the sacculina and the crab, by MM. Louis Bruntz and Jean Gautrelet.—On some fossil pollens, male prothallia, pollenic tubes, &c., in the Coal-measures, by M. B. Renault. Many pollen grains of the coal epoch contain a perfectly well-marked male prothallus, the compartments of which contain the mother cells of the antherozoids. This prothallus may emit a pollen tube, as in Stephanospermum, or allow the antherozoids to escape directly from the pollen chamber, as in Aetheotesta.—The influence of cream separation on the principal constituents of milk, by MM. F. Bordas and Sig. de Raczkowski. The removal of the fat to the extent of 98 per cent. takes away at the same time 69 per cent. of the lecithin. In the authors' opinion, this is sufficient to explain the high death-rates through gastro-intestinal troubles in those towns where the sale of skimmed milk is allowed. It also accounts for some diseases in infants fed exclusively on sterilised milk.—On the physical geography of the Western Vaila, Crimea, by M. E. Daniloff.

DANGEROUS TRADES.

Dangerous Trades: the Historical, Social, and Legal Aspects of Industrial Occupations as affecting Health. By a number of Experts. Edited by Thomas Oliver, M.D. (London: John Murray, 1902.)

IT is claimed for this volume of some 900 closely printed pages that it constitutes the first serious attempt in this or indeed any other country to deal comprehensively with the conduct of trades in relation to the life and health of the workers. And there is a certain fitness in the fact that such a book should first be produced here and that its authors should be British, inasmuch as Great Britain has led the van in factory legislation as she has hitherto led it in industrial enterprise. Industrial enterprise and the economic and social amelioration of the worker inevitably go together, for in proportion as each country advances in commercial prosperity and in economic development, higher ideals of comfort and higher standards of industrial hygiene are demanded by its people. Our own legislative attempts to secure these began with the opening years of the last century, and have been made the basis of, and the occasion for, similar attempts abroad. The general result has been that during the last forty or fifty years the lot of the artisan has been everywhere brightened by the improvement of the conditions under which much of his labour has to be performed.

It is hardly necessary to say that such a measure of progress has only been obtained by strenuous and persistent effort, by outside interference, or in other words, by the working of the public conscience and the force of public opinion.

Apathy, callousness, self-interest and an obstinate adherence to the doctrines of a perverted political economy have too frequently stood in the way of well-recognised reforms. It must be admitted that much of the improvement has been contemporaneous with the shifting of political power, but whether as the direct result of it is by no means equally certain. The spread of information, a more enlightened self-interest on the part of the worker, the organisation of labour, a deeper and more active sense of public responsibility in regard to unhealthy trades, together with an intelligent appreciation on the part of employers that what is good for the bee is also good for the bee-hive, have combined to secure the good which has been achieved.

The book before us is made up of sixty chapters—so many separate essays, in fact—contributed by thirty-eight authors, all of whom must be considered specialists on the subjects with which they deal.

It is impossible within the space at our disposal to do more than indicate in the briefest possible way the main features of the mass of material which Dr. Oliver and his coadjutors have brought together. We hope, however, to succeed in showing that the work deserves the careful attention of everyone interested in the hygiene of industrial life—employers of labour, factory inspectors, certifying surgeons, and also of the many members of our Legislature who concern themselves with the well-being of our artisan population. It is not to be expected that all will give unqualified assent to every expression of opinion to be found within the work. The various questions of public policy which are incidentally raised are necessarily subjects of controversy, and will be viewed very differently by persons of different political proclivities or of different schools of economics. But we think that every dispassionate and impartial reader will admit that, taking it as a whole, it is a conscientious and praiseworthy attempt to deal with matters which lie at the very foundations of our industrial prosperity and happiness.

In an introductory chapter Dr. Oliver traces in a few short paragraphs the main features of the industrial revolution—the change from the domestic system of industry to the modern methods of production by machinery—which constitutes one of the most momentous epochs in the history of our civilisation, and he indicates the changes in the social and intellectual condition of the people to which it has directly and indirectly given rise. He explains how a demand for the State control of our industries so far as relates to the safety, health and moral condition of the workers has arisen, how it has been met, and within what limitations the control has been operative and effective. As regards the economic effect of factory legislation, Dr. Oliver utters no uncertain sound.

"Those who blame State interference as the cause of the doubtful decline of our industrial supremacy, and who believe that it is checking enterprise, are not making a sufficiently serious attempt to grapple with the question by sifting all the facts carefully. It can be demonstrated that legislation has not paralysed but has improved trade as well as the conditions of labour."

He is no less reassuring as regards the results which have flowed from the Workmen's Compensation Act:—

"The Workmen's Compensation Act," he says, "which was so strongly opposed by many employers on the supposed ground that it would ruin the industries of this country, has had apparently no effect in that direction. Although it has theoretically increased their financial liability, as a matter of fact many employers have been less out of pocket than formerly. The Act has cleared the industrial atmosphere, made employers more careful in their selection of workmen, more willing to safeguard machinery, and do all they reasonably can to prevent accidents. It pays them to do so."

Should the Act be extended so as to include a larger number of industries and more particularly those regarded as dangerous trades? On this point opinions may differ, as was shown by the fate of the proposal in Parliament to place industrial diseases on the same footing as accidents.

The main objection would seem to depend upon the difficulty of defining industrial diseases.

"For a disease to be regarded as industrial, and capable, therefore, of being brought within the scope of the Workmen's Compensation Act, it would have to be placed upon the same narrow limit as an accident. It would require to be shown that it was the sole result of the occupation, and that there had been produced a definite pathological lesion of the body. Adopting this view, the maladies that could be included in the category would be, among others, anthrax, poisoning by lead, mercury, phosphorus, and bisulphide of carbon; but with the exception of anthrax, in which the disease is often

suddenly induced, and as rapidly runs to a fatal termination, there is not as a rule the same exactitude in the incidence of disease as is the case in accident. There might be little difficulty in including anthrax under the Act of 1897. The inclusion of some of the other dangerous trades would give rise to frequent litigation, but it would make employers more careful in the selection of their work-people, and in the means adopted to prevent industrial poisoning."

Among the most thoughtful and suggestive of the essays contained in the work are those contributed by the lady inspectors of factories. Miss Anderson's "Historical Sketch of the Development of Legislation for Injurious and Dangerous Industries in England," and her chapter on the "Regulation of Injurious or Dangerous Occupations in Factories and Workshops in Some of the Chief European Countries," are especially noteworthy for their breadth of view, thoroughness and impartiality. The one chapter, in fact, may be regarded as complementary to the other. Comparing what has been done abroad with the position at home, H.M. Principal Lady Inspector comes to the conclusion that England is lagging behind.

"England stands in a special position, with its own qualities and defects. Having entered long before most other European countries on the path of control of employment in factories owing to the earlier need of such regulation, and having admittedly also led the way in the task of building up a complete and precise sanitary code for regulation of public health, England has shown in the later stages of the part of the work which touches industry too little interest in the later efforts, on different lines, of other countries. This slowness is traceable in part to the same causes as those which have retarded in England the general study of comparative legislation and administration, of which foremost, no doubt, stands the necessity of developing on national lines our own safeguards, yet it seems probable that the country which in a singular degree stimulated European progress in public health by the justly famous "Report on the Sanitary Condition of the Labouring Population," 1838, has latterly retarded its own progress in industrial hygiene by too close an adherence to its own methods."

Again :—

'In several of these [foreign] countries, all of which had originally to some extent looked to the far earlier example and experience of England in enforcement of the law, the important step was taken, considerably in advance of England, of bringing into the factory service medical, engineering, and chemical expert knowledge. No doubt in England, the delay in this matter is directly traceable to the character stamped on the institution by the educational, moral and social origin of our Factory Acts, and to the very recent beginnings of development (1883–1891) of a special basis of factory hygiene."

In one respect, however, England compares favourably with continental nations in the completeness of its statistics in regard to industrial poisoning. As Miss Anderson points out,

"In no other country has the step been taken of laying both on the occupier of a factory or workshop and every medical practitioner the duty of reporting to a chief inspector of factories, or the central authority, individual cases of industrial poisoning.

On the other hand, in no other country is there "a power reserved to employers," similar to that which was in force in England until last year, "of compelling such objections as they can sustain to proposed rules to be settled by arbitration." What Parliament and the country thought of the manner in which arbitration had worked in the past was seen in the practical unanimity with which this form of procedure was swept away in 1901.

In a short chapter on the "Principles of Prospective Legislation for Dangerous Trades," Mr. Tennant, the chairman of the Dangerous Trades Committee, which presented its final report in 1899, deals more especially with the question of the amendment and consolidation of the law relating to factories and workshops, the history of which has this in common with that of the British constitution, that "the structure of each is compounded of small accretions, contributed by what seemed the necessity of the moment." In the present condition of the law there are unquestionably many incongruities and anomalies—exemptions difficult to justify and exceptions incapable of rational explanation. But whilst much of the practical force of Mr. Tennant's contention has been minimised by the transference, above alluded to, of the responsibility for the special rules from an arbitrator or umpire to the Secretary of State, the doubt still remains whether the main defects of the present system are altogether remedied.

Chapter v. deals with the influence of factory labour upon infant mortality, and is made up of two essays, one contributed by Mrs. Tennant, formerly H.M. Principal Lady Inspector of Factories, and the other by Dr. Reid, the Medical Officer of Health of the Staffordshire County Council. Each of these essays tells the same tale, and a sad enough story it is. We heard a good deal some little time since about "the holocaust of babes" in the concentration camps in South Africa, but the waste of infant life there was out of all comparison with that which goes on unchecked as the result of our own factory system. A former Lord Londonderry once railed against the "hypocritical humanity" of Parliament when it sought to protect the lives and limbs of coal-miners. We may hope that Parliament will not continue to turn a blind eye to the large amount of infant suffering and the terrible waste of child-life in our manufacturing towns, but will learn to recognise before it is too late that, as Sir John Simon once said, "a high local mortality of children must almost necessarily denote a high local prevalence of those causes which determine the degeneration of the race."

The exigencies of space only allow of a passing reference to Miss McMillan's essay on "Child Labour" and to that by Mr. Ballantyne on "Home Work." Happily the half-time system is dying out and the age of the full-timer is being steadily raised. The question of home or out-work is one of great difficulty, and there is much in it which calls for State regulation. But it would require a strong Minister with a strong public opinion behind him to deal with it at all adequately.

The editor contributes a short paper on the "Physiology and Pathology of Work and Fatigue," in which he treats of the means of measuring muscular work, the changes which occur in tired muscle and in the blood of fatigued persons, the effect of work on nerve structure, the use of alcohol as a muscle food, &c. Although appealing more particularly to the physiologist, the

article is not too technical, and its style is appropriate to the work in which it appears. It is, perhaps, not undesirable that those who regard men and women as "hands"—that is, as machines for turning out work—should have some knowledge of the pathological consequences of fatigue.

Dr. Tatham's paper on "Mortality of Occupations" deals briefly with matters which have already been more fully treated by him and others in official publications, notably in the successive decennial supplements to the reports of the Registrar-General. In the chapter on "Dust-producing Occupations" he considers more particularly those industries which give rise to the constant inhalation of dust, leading to grave and characteristic lesions resulting in premature breakdown and death among the workers, and in a subsequent section he discusses the effects of the accumulation of respiratory and other impurities in the air breathed, partly from the neglect of suitable methods of ventilation and partly as the result of the cramped position adopted in certain cases of sedentary indoor labour.

Dr. Oliver also contributes a chapter on "Dust as a Cause of Occupation Disease," with special reference to the skin diseases of flax-workers and the diseases of the nails among furriers, lung diseases, and gastro-intestinal lesions attributable to dust.

The chapter on "Dustwomen" is curious and interesting, and serves to show how the dangers due to what is a disagreeable and at times even a disgusting employment may be mitigated by the conditions under which the work is performed if only a little common sense and prudence are exercised.

By far the greater portion of the work is concerned with the effect of particular industries upon the health or longevity of the worker, and it is this section which will appeal most strongly to individual employers, to statisticians and to the practical legislator. Mr. Cunynghame contributes an interesting article on the history of the attempts which have been made by the Board of Trade and by Parliament to bring the dangerous operations on railways under regulations analogous to those which can be made by the Home Office in regard to the dangerous processes in factories and mines. Although time can alone show how far Mr. Ritchie's attempt to bring railway labour within the circle of protected industries will actually realise the anticipations held out at the time of the passing of his Act, there can be no question that the position of railway servants as regards immunity from accidents has been thereby greatly ameliorated.

The extraordinary development of the technical applications of electricity has brought a special crop of dangers to the workers in its train, which are dealt with by Commander Hamilton Smith, who also contributes a chapter on acetylene and its dangers.

Lead and its compounds are naturally dealt with by the editor, who also treats of china and earthenware manufacture and of phosphorus and lucifer matches—subjects with which he has specially concerned himself at the instance of the Home Office. Mr. Malcolm Morris furnishes a short chapter on the industrial employment of arsenic; Dr. Legge contributes one on the dangers in the use of mercury and its salts, and one on the lesions resulting from the manufacture and uses of the alkaline bichromates. The effects of the dust of basic slag, and that resulting from ganister crushing and from buhrstone chiselling, are also treated in special chapters. Steel grinding is dealt with by Mr. Sinclair White, who, as a lecturer connected with the medical department of University College, Sheffield, has special opportunities of acquiring information; and the subject of "brass ague," which is particularly prevalent in Birmingham, the home of the brass trade, is treated by Dr. Simon, of the General Hospital in that city.

The dangers incidental to the use of bisulphide of carbon and naphtha in the manufacture of indiarubber and of benzene in dry cleaning are considered by the editor, who in this connection might also have had regard to the use of carbon bisulphide as a wool cleansing or degreasing agent. Dr. Prosser White, who is officially connected with the Roburite Explosives Company, contributes a chapter on the effects of dinitrobenzene and other nitro-substitution products on the workmen employed in the manufacture of high explosives. The effects of such explosives on the air of mines, together with the general pathological results of breathing the atmosphere of mines, are considered by Dr. Haldane, who is specially well qualified by experience and observation to deal with the subject. Principal Laurie treats of the health of workers in chemical trades; Drs. Hamer and Bell furnish two essays on anthrax and its relation to the wool industry; and Mr. Stuart, who is the medical officer of health at Batley, contributes chapters on blanket stoving and on rags and their products (shoddy mungo, &c.) in relation to health. The woes of the washerwomen—and they are more grievous than many of us are aware—are sympathetically dealt with by Miss Lucy Deane; whilst Miss Paterson tears aside something of the romance which seems to environ the life of the braw fishwife "bearing with apparent ease the enormous creel of fish and her almost equally surprising burden of petticoats." We do not usually associate much that is unhealthy either with the occupation or the appearance of the stalwart lassies that make such a picturesque congregation on the quays of Stornoway, Peterhead or Lerwick. But that the "kipperer" and the "gutter" have their peculiar troubles, and that these may be avoided by definite enactment and administration, with regulated hours and sanitary work places, are equally certain.

There is much else in the book that we should have liked to indicate and many excellent features upon which we could have wished to dwell at greater length. If we have a fault to find it is that it includes too much. The diseases of soldiers at home and abroad and questions of marine sanitation hardly come within the province of a work entitled "Dangerous Trades." Admirable as the articles relating to these subjects are, we think the editor would have been well advised to keep to subjects which are strictly within the purview of the Home Office. No doubt it is an all-embracing Department, but if the profession of arms is to be regarded as a dangerous trade in the sense that the occupation of the potter or the wool-sorter is considered dangerous, it is not easy to see why that of the medical man, the journalist, or even the legislator should not equally have been included.

We venture to think, too, that the work suffers to some extent by the mode in which its parts have been put together. It is necessarily somewhat mosaic in character, and there is a certain want of harmony and continuity of arrangement. No doubt this is due to the difficulty of dealing with so large a body of contributors, all of whom are working independently. But these, after all, are minor blemishes, and do not seriously detract from the very great value of the compilation. We heartily congratulate Dr. Oliver and his colleagues on the production of a work which will unquestionably take high rank in the literature of sanitary reform.

T. E. THORPE.

THE NEW INTERNATIONAL CATALOGUE.

International Catalogue of Scientific Literature. First Annual Issue. D. Chemistry, Part i. Pp. xiv + 468. (1902.) Price 21*s*.

THIS is the second instalment of the work of the International Catalogue Bureau, the first (part i. of Botany) having been reviewed in our issue of July 3 (p. 217). In a notice on p. xiv. it is explained that in consequence of the difficulties attending the complete organisation of the work of the regional bureaus some delay has arisen, and it is hoped that the second part of the volume will be published in a few months. In starting a colossal work such as this "International Catalogue," delay was inevitable, and it is to be hoped that when the different bureaus are in working order the volumes will be published more closely to the period to which they refer. On the title-page it is stated that the MS. for this volume was completed in January, 1902, so we presume that both parts i. and ii. will deal with the year 1901 only.

It is reported that although the seventeen annual volumes which constitute the "Catalogue" will, as a rule, contain the work of twelve months, yet they will not all refer to one calendar year; probably it is impossible to avoid this arrangement so as to maintain the work of the Central Bureau at a uniform rate, but it would certainly be convenient to scientific workers if, for each science, all the papers of one calendar year could be collected into one volume. No doubt the title-page of each volume will indicate the period over which the papers indexed extend, but the annual arrangement, if practicable, would appear to be much more convenient.

The authors' catalogue is contained in 111 pages with 2455 entries; in this the authors' surnames are printed in Clarendon type with the Christian names in Roman; when initials only are given in the original paper, the remainder of the name is placed in square brackets; when a paper is by more than one author, only the name of the first is in thick type. The complete title is given, usually in the language in which the paper is written. In the case of languages other than English, French, German and Italian, a translation of the title in one of these four languages follows the original; in some instances, however, translations only are given, the names of the original languages being placed in brackets. Then follow the abbreviated titles of the periodicals, with the complete reference to volume, year and pages of beginning and ending of the paper, the number of the pages being in parentheses. The registration numbers are placed in square brackets, and when the papers deal with other sciences in addition to chemistry, the letters and registration numbers of these sciences are included. The papers are numbered consecutively, these numbers concluding the entries. At the commencement of the volume, the schedule of chemistry, with registration numbers, is printed in English, French, German and Italian; and at the end there is a list of the periodicals with their full titles and the abbreviations used in the "Catalogue."

The subject catalogue occupies 283 pages, and is arranged in the order of the registration numbers. At the top of each page the registration number is given in thick type and is easily seen. Each division is marked with the registration number and the corresponding subject as a heading. The numbers are here also printed in thick type and the subject in Roman capitals, but they do not catch the eye so well as could be wished; the subsidiary titles are in Clarendon with capital initials, and are more easily seen than the heading of the division; thus on p. 195 the heading "Zinc Oxide" is very visible, whereas the heading "Zinc" at the commencement of the division is not so clearly shown.

In the subject catalogue the entries are, as a rule, reprints of the corresponding entries of the authors' catalogue, commencing with the authors' names in Clarendon and, if the papers belong to more than one division, concluding with the registration numbers other than those of the division under which the entries are made. The entries are repeated under each registration number. As in a subject catalogue the authors' names are not of the first importance, it would be better, if it were possible, to give prominence to the subject. The title of a paper does not always indicate its contents, and we are glad to see that in many of the papers from English serials a title is given in square brackets which shows much more effectually the contents of the papers than the original heading; thus in the authors' catalogue occurs the following entry:—"Frankland, Percy Faraday and Farmer, Robert Crosbie. Liquid Nitrogen Peroxide as a Solvent. London, *J.* Chem. Soc., 79, 1901 (1356–1373) . . . . [0490 7100 7250]" In the subject catalogue under "0490 Nitrogen," subdivision "Nitrogen Oxides," the same entry occurs, with the registration numbers [7100 7250]. Under "7100 Mass Properties," subdivision "Molecular Weights," after the names of the authors there follows "[Molecular weight determinations in liquid nitrogen peroxide by the ebullioscopic method]," with the registration numbers [0490 7250]. Under "7250 Electrical and Magnetic Properties," subdivision "Conductivity, e find the names followed by "[Conductivity of solutions in liquid nitrogen peroxide]," with the numbers [0490 7100]. It will be seen that the last two subjects cannot be inferred from the title of the paper, and there must be many other cases of the same kind. The subject catalogue is much increased in value by this indication of the contents of the papers, for which we are indebted to the activity of the English Bureau, or perhaps more definitely to that of Mr. Ernest Goulding, the referee for this volume. It would be a great boon if the other regional bureaus could be induced to give this partial analysis of the papers. It may be replied that the fact of the reference being placed under

certain subdivisions would sufficiently indicate the contents of the paper, and in the case above cited this is partially true; but take the paper numbered 738 and compare its title with those under the various sections (they are too long to quote), and the value of the additional titles will be at once appreciated.

Of recent years our knowledge of organic chemistry has increased so rapidly that it might be difficult to know under which registration number to look for some of the organic compounds, and chemists will be thankful to the Central Bureau for giving a list of organic bodies and their registration numbers extending over nearly sixteen pages in double columns and containing some 1800 references.

It may be thought that the mode of using the registration numbers would be very difficult to acquire, but it is surprising how rapidly one becomes accustomed to their employment after a little practice. It cannot be said that the schedules as they now stand are perfect, but when they are revised in 1905 many emendations will doubtless be made.

We must be thankful to the Central Bureau for the care and accuracy with which this volume has been compiled, and we must congratulate chemists on having another instrument of research at their disposal.

HERBERT McLEOD.

ANOTHER THEORY OF SEX.

Qu'est-ce qui détermine le Sexe? Par le Docteur A. Van Lint, Médecin Assistant à l'Hôpital Saint-Pierre, à Bruxelles. Pp. 77. (Paris: Baillière et Fils, 1902.)

DR. A. VAN LINT has convinced himself of the validity of a somewhat extraordinary new theory as to the determination of sex, which is in some measure a rejuvenescence of Starkweather's. If it is true, it should give pause to virile fathers who wish to have sons, for unless they can secure still more vigorous mates they are sure to have daughters only. The theory is, that the offspring follow the sex of the weaker parent, though, as we read on, this turns out to mean the parent whose available germ-cells are relatively less vigorous at the time of fertilisation. But an attempt to estimate the relative vigour of germ-cells leads us into the region of the unverifiable.

To understand the author aright we must note that he does not believe in the concept of the germ-plasm ("pour nous, les cellules génitales se développent tout entières aux depens des cellules somatiques," p. 34), and that he postulates the origin of the unisexual organism from primitive hermaphroditism, a tendency to which always persists in more or less subtle guise. We cannot within our limits argue about these postulates, but we cannot agree with either. It is very interesting to compare van Lint's views with those stated by Dr. John Beard in his paper on the determination of sex, also published this year.

Van Lint's new theory is a coordination of five hypotheses, which he expounds in a lucid and suggestive manner:—(1) The ovum and the spermatozoon are antithetic, expressing opposite extremes of cellular differentiation, and perhaps analogous to right-handed and left-handed crystals of the same stuff. (2) There is also a somatic antithesis between the masculine body and the feminine body, often conspicuous in the so-called secondary sex-characters, often inconspicuously expressed in minute contrasts which saturate the whole soma. (3) Again, there is an antithesis between the character of the germ-cells borne by an individual and the character of the body of that individual; they are complementary expressions of the primitive hermaphroditic unity of the organism; indeed, the characters of the sex suppressed in the development of the unisexual gonads are expressed, as it were, in pervasive influence on the soma. (4) So strong is this third antithesis that the male's somatic cells—which the author in a question-begging term calls "parovules"—may be regarded as sexually equivalent to ova; while the female's somatic cells—which the author in another question-begging term calls "paraspermatozoides"—may be regarded as sexually equivalent to spermatozoa. This seems an extravagant and unwarranted hypothesis, and we are quite unconvinced by the facts as to effects of castration, &c., adduced in support of it. But to continue. (5) The properties of the "sexualised" body react on the properties of the germ-cells, in embryonic as well as in adult life, and this in such a definite way that they determine the sexual bias, or the sex of the offspring into which the germ-cells will develop. In short, the sex of the offspring depends on the relative bodily vigour of the parents.

Thus, if a relatively feeble ovum be fertilised by a relatively vigorous spermatozoon, the spermatozoon's qualities will be dominant; the embryo will therefore have (by hypothesis) a masculine or "paraspermatozoid" body, and to balance this the gonads will be female. One naturally wishes to know what the relative vigour of a cell means, and this is discussed in chapter v.; one also wishes to know how the vital force of a parent is measured, and chapter vi. gives the six heads of a complete medical examination. We are relieved to find, however, that the certain sign that a man is more vigorous than his wife is his having a daughter. "Le sexe de l'enfant tranchera la question." Could there be a more conclusive criterion?

In the seventh chapter it is shown that the author's theory fits in well with the phenomena of "crossed inheritance." The son is the result of a more vigorous ovum fertilised by a less vigorous spermatozoon; the somatic cells must balance the gonads, therefore they must be feminine, and, of course, the boy is the image of his mother. Could anything be simpler?

In the eighth chapter the author seeks to show with great ingenuity that the available statistical and experimental results on this difficult subject may be harmonised with his views, and concludes by showing that the so-called auto-regulation of the proportions of the sexes is also explicable on his theory, according to which it is always the more feeble that Nature insists on replacing. If we had space at our disposal we should be delighted to disagree with the ingenuous author in regard to the detailed facts, but it would be of little avail since we cannot admit his postulates. The moral of the book seems good—that the strong man who wishes to have sons must find a still stronger mate; but it also follows, unfortunately, that the weak woman who does not wish

to have daughters has no resource but to find a still weaker husband. The thesis, if accepted, should beget humility in those male parents who have large families of lusty sons.

J. A. T.

RÖNTGEN RAYS IN MEDICINE AND SURGERY.

The Röntgen Rays in Medicine and Surgery as an aid in Diagnosis and as a Therapeutic Agent. By Francis H. Williams, M.D. (Harvard). Pp. xxxii + 704; 401 illustrations. Second edition, with appendix. (New York: The Macmillan Company; London: Macmillan and Co., Ltd.) Price 25*s.* net.

THE second edition of this excellent work was called for because the first was unexpectedly exhausted within three months, and we congratulate the author upon his deserved success. Only those acquainted with the subject can appreciate how difficult it is for any author to give a correct view of the progress of such a branch of science as the X-rays, because of the great advances made within a comparatively short period, the number of authors engaged in research and the nature of the subject itself. As might have been expected, Dr. Williams fully understands this, because in his preface he states that the work is rather a report of progress than a final presentation of a growing subject. Further, owing to the short time at his disposal for the preparation of a second edition, he has only been able to add some forty pages, chiefly on apparatus and the therapeutic uses of the X-rays. This will be found in the appendix.

Dr. Williams very properly introduces his subject by reference to the principles of physical science, and, without overburdening the student, he tells what is necessary for their appreciation. Next he deals in the most practical way with the equipment necessary for photographic and therapeutic work. Having thus prepared the way, he enters into a full description of the normal conditions of the cavities of the body so that the observer may be able to appreciate deviations from the normal, a principle which will be thoroughly appreciated by all those who are seeking for information from the clinical aspect. The pathological changes are well described by photographic illustrations, diagrams and histories of selected cases.

A noticeable feature of the work is the amount of attention devoted to what might be called the medical aspect of the subject as opposed to the surgical. This is interesting, because for a long time many who believed in the value of X-rays in the detection of fractures, dislocations of the hard structures and foreign bodies were inclined to think that the use of X-rays would be limited to these. If any are still of this opinion we commend them to a perusal of this work.

The third great step in the development of X-rays in medicine was their application in diseased structures, and the present position of their therapeutic action is frankly and fairly stated in these pages.

While it is true that the work gives a very strong representation of the methods employed in America—indeed, the illustrations themselves show that the work has not been produced in any European laboratory—still the labours of others have not been neglected. In future editions the work might be enhanced in value by a reference to what has been done in this country and the European schools of medicine, a fact which is admitted by the author in his preface, because he states that he had intended to include as complete a list as possible of the publications on the subject. This was not found possible on account of its extent, so he adds that had he foreseen this he would have referred in the text to many other important papers.

The work is well written by one thoroughly familiar with the subject, is profusely illustrated, and to those who desire a guide to the study of the subject the work may be thoroughly recommended; and this remark applies to students and practitioners.

OUR BOOK SHELF.

Elementary Geometry. By W. C. Fletcher, M.A., Head Master of the Liverpool Institute; late Fellow of St. John's College, Cambridge. Pp. 80. (London: Edward Arnold, n.d.) Price 1*s.* 6*d.*

THIS is a very small book and a very good one. Its object is to teach geometry to boys without hindering and wearying them with metaphysical subtleties, or requiring them to express the proofs of propositions with that pedantic recitation of details—that parody of logical accuracy—which has long been identified with the study of Euclid.

The author is perfectly correct when he says that his little book "contains the whole substance of Euclid i.–iv. and vi. except the elegant but unimportant proposition, iv. 10."

The branches of the subject are taken in the following order:—Angles, triangulation (*i.e.* the discussion of the properties of triangles), quadrilaterals, loci, proportionals, circles, tangents, areas, maxima and minima, this last section being very short and merely illustrating what is meant by a maximum or a minimum. There is no formality whatever in the proofs, the most simple propositions being often left to the student with a hint sufficient for the solution. Each section, besides terminating with a number of simple exercises (well within the power of the beginner), contains a number of numerical illustrations to be worked by actual drawing with instruments. This is precisely the kind of teaching which is now being advocated by those who have taken up the question of the reform of mathematical teaching.

In propositions relating to proportion—as, for example, that a line drawn parallel to the base of a triangle divides the sides in the same ratio—the author explicitly states that he assumes two magnitudes to have a common measure, and that the difficulty which arises in the case in which they have not "had better be disregarded for the present." The reason for thus making an *essential* difference between "commensurable" and "incommensurable" quantities of the same kind is not obvious, since any proposition which holds for the former will be admitted, even by the beginner, to hold for the latter when it is pointed out that the unit magnitude may be taken so small that the distinction between commensurable and incommensurable quantities practically disappears. The proposition that the sum of two sides of a triangle is greater than the third is proved by the definition of a right line as the shortest distance between two points. The nature of a tangent as the limiting position of a chord is that which the author adopts. This also is in accordance with modern notions, and it offers no difficulty whatever even to the merest beginner. In p. 42, line 4, for "place them so that two pairs of sides are parallel,"

read "place them so that any two corresponding sides are parallel." In p. 63, ex. 19, for "prove also that OT, ON equal OP^2," read "prove also that OT.ON equals OP^2."

Diagrams of Mean Velocity of Uniform Motion of Water in open Channels, based on the Formula of Ganguillet and Kutter. By Prof. Irving P. Church. 11 Diagrams + 1 page Text. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1902.)

THIS little work, in spite of its ponderous and somewhat ambiguous title, is a useful and workmanlike collection of curves from which may be obtained the value of the mean velocity v in the empirical formula $v = c\sqrt{rs}$, so much used in computing the flow of water in channels.

To the ordinary reader the term "mean velocity of uniform motion" is puzzling; but anyone versed in hydraulics will understand that the author wishes, very properly, to restrict the application of his curves to cases where the rate of flow is constant, *i.e.* where the same number of cubic feet or gallons pass a given section of a channel of uniform cross-section every second.

In the formula the trouble is with the coefficient c, which is not independent of r and s—the hydraulic mean depth or "hydraulic radius" and the slope. The coefficient may be computed, for channels of different materials, from well-planed timber to earth and stones, by the formidable law of Ganguillet and Kutter,

$$c = \frac{\dfrac{1\cdot811}{n} + 41\cdot65 + \dfrac{\cdot00281}{s}}{1 + \dfrac{n}{\sqrt{r}}\left(41\cdot65 + \dfrac{\cdot00281}{s}\right)},$$

where n is the arbitrary constant which ranges in value from 0·009 to 0·035 in the two extreme cases cited.

Very few people, we imagine, actually calculate c in this way, as tables by Trautwine and others give its value for all likely values of n, r and s. Prof. Church has, however, gone a step further, and his diagrams give values, *not* of c, but of v, thus avoiding the further calculation usual after c is found from tables.

There are eleven diagrams, each corresponding to a particular value of n, the vertical lines in each diagram showing "slopes," inclined lines "hydraulic radii," and horizontal lines "mean velocity" v. The intersection of any three of these lines satisfies the relations referred to, and shows for the selected values of n, r and s the required mean velocity in feet per second, which, multiplied by the cross-sectional area of the channel in square feet, gives the flow in cubic feet per second.

A test or two, worked out from the formulæ, shows the curves to be accurate enough for practical purposes.

Thus, selecting $n = \cdot01$, $r = 10$, $s = 2\cdot0 \div 1000$, the calculation gives

$$c = \frac{\dfrac{1\cdot811}{\cdot01} + 41\cdot65 + \dfrac{\cdot00281}{\cdot002}}{1 + \dfrac{\cdot01}{3\cdot162}\left(41\cdot65 + \dfrac{\cdot00281}{\cdot002}\right)} = \frac{224\cdot155}{1\cdot136} = 197\cdot3$$

and

$$v = 197\cdot3\sqrt{10 \times \cdot002}$$
$$= 27\cdot89 \text{ feet per second.}$$

The diagram gives v about 28.

In another test where $n = \cdot03$, $r = 10$, $s = 2\cdot0 \div 1000$, the diagram gives v about 10·5; calculation makes it 10·38.

There is no doubt, therefore, that Prof. Church has compiled a real "labour-saver" for those who have to make numerous calculations of the kind referred to.

Near the end of the author's explanation he mentions the application of the diagrams to cylindrical pipes and sewers "running full or half-full." We would point out that the rule $v = c\sqrt{rs}$ is not applicable with success to pipes running full, though various American writers attempt to use the law in this sort of universal sense. Much more authentic formulæ are available for calculating the flow in pipes, and the curves given in this little work should not be applied to that purpose. R. G. B.

A First Course of Chemistry (Heuristic). By J. H. Leonard, B.Sc. Pp. vi + 134. (London: John Murray, 1902). Price 1*s*. 6*d*.

THIS little work provides a course of elementary chemistry resembling the well-known course which was drawn up some years ago by Prof. Armstrong and endorsed by a British Association committee. Great pains are taken to make the teaching undogmatic and to imbue the pupil with the zeal of a scientific inquirer. The topics include a study of chalk, lime and carbonic acid, air, water, combustion, acids and salts. Though the work cannot be pronounced superior to some that have already been written with the same object, it gives a good representation of what many people now think the right way of approaching elementary chemistry. On any system the teaching of elementary chemistry will for long remain full of difficulties and inconveniences. We notice that on p. 43 there is an instruction to collect oxygen by displacing air in an inverted cylinder, and on the next page an experiment, correctly enough described, perhaps, leading to the conclusion that oxygen is lighter than air. A. S.

An Elementary Book on Electricity and Magnetism and their Applications. By Profs. D. C. Jackson, C.E., and J. P. Jackson, M.E. Pp. xi + 482. (New York: the Macmillan Company; London: Macmillan and Co., Ltd., 1902.) Price 7*s*. 6*d*.

THE object of the authors has been to write a book which will serve both as an elementary text-book and as an interesting account of the subject for the general reader who has a taste for the science. With this in view they have naturally taken industrial development as a guide, and wherever possible have shown the connection between the simple principles of the science and their technical applications. As the general reader is usually ill-equipped with mathematics, we find that little more than the simplest equation is used in the book.

Each chapter is followed by questions. Here are some of the questions which come at the end of the first chapter:—

"How much is known about the real constitution of electricity?"

"What is electricity supposed to be by some scientists?"

"What kind of electricity will a positively charged ball induce?"

The book contains twenty-three chapters, and from chapter xv. to the end the subject-matter is principally technical applications. Thus polyphase motors, electric welding, cooking and Röntgen rays, and other new uses are each described in their appropriate chapters.

S. S.

The Face of Nature. By the Rev. C. T. Ovenden, D.D. Pp. ix + 188. (London: John Murray.) Price 2*s*.

IN this little volume we have the material for several "popular readings in elementary science," the subjects of the four chapters being weather forecasting, vegetable life, the record of the rocks, and stones from boulder clay. The village clergyman or teacher who desires to show that there are "sermons in stones" and other natural objects and phenomena will find Canon Ovenden's short addresses of service.

A few points will, we think, lead to misconception if accepted as they now stand. For instance, a barometer is said to weigh the air, whereas it really measures pressure. Again, it is only true in the northern hemisphere that a "cyclone spins always against the hands of a clock, and the anticyclone rotates with the hands of the clock."

In the chapter on plants, roots are said "to suck up water through tiny mouths," "to search for lime salts," and "to pick up compounds of potash." Of some plants we read, "They determined to do by cunning what they could not accomplish by force," "One very clever tree seems to have foreseen this danger and provided a remedy." "The hazel never intended to grow nuts either for boys or squirrels." "The pitcher plant and Venus's fly trap which set most ingenious snares for insects, and devour them when caught."

The point of view of the whole of this chapter is unscientific, for plants do not do any of these things intentionally, and to attribute intelligence to them is misleading.

The illustrations are line drawings enclosed in circles for reproduction as lantern slides. In many cases a scale should have been provided. The diagram of a bean seed (p. 49) is very poor.

Gold Seeking in South Africa: a Handbook of Hints for intending Explorers, Prospectors and Settlers. With a chapter on the Agricultural Prospects of South Africa. By Theo Kassner. Pp. x + 134; with maps and illustrations. (London: Charles Griffin and Co., Ltd., 1902.) Price 4*s.* 6*d.*

NOW that a new era is opening in South Africa, the appearance of any book giving information likely to be useful to intending immigrants is opportune. It will not be taken for granted by everyone that the last discoveries of gold in the Transvaal have already been made, and the venturesome prospectors who go there should include this little book in their outfit, as it is written by one who knows the country well. It contains some useful notes on the geology and history of the Transvaal goldfields, and a number of sketch maps. The De Kaap goldfield is treated somewhat more at length than the others, although even this account can hardly be called exhaustive. The illustrations are numerous, but a protest must be made against the inclusion of some of them, particularly of Fig. 6, which is said to represent a pestle and mortar.

A Text-Book of Inorganic Chemistry. By Dr A. F. Holleman. Rendered into English by Hermon C. Cooper. Pp. viii + 458. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1902.) Price 10*s.* 6*d.*

THE German edition of this Dutch work was noticed in NATURE, vol. lxii. p. 598, October 18, 1900. A reperusal shows that considerable improvements have been made in the English version. The translation is entirely satisfactory, and the book may be recommended as a lucid and scientific account of inorganic chemistry. It includes a great deal of well-expounded physical chemistry and also many incidental matters of interest that are not usually found in works on inorganic chemistry. It is likely to prove very acceptable to those who wish to have a moderately advanced book of inorganic chemistry embodying an unaggressive presentation of the most modern discoveries and theories.

The Bernese Oberland. By G. Hasler. Vol. i. From the Gemmi to the Mönchjoch. Pp. xxv + 164. (London: T. Fisher Unwin, 1902.) Price 10*s.*

THIS is the first volume of a series of four intended to guide climbers to the peaks and passes of the High Alps of the Bernese Oberland. The routes are arranged in chronological order of the conquest of the peaks to which they lead, and are dealt with in six sections referring to the Balmhorn, Breithorn, Blümlisalp, Bietschhorn, Aletschhorn and Jungfrau groups. With this guide in his pocket, a climber will be able to explore districts which, happily, have not been entirely permeated by the show and tourist spirit characteristic of more frequented spots, and are full of interest.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Archæological Remains on the Summit of the Nevado de Chañi.

DURING the excursions that were made under my direction in 1901–1902 in the north of Argentina and the south of Bolivia from the Puna de Atacama to Crevaux at Pilcomayo, some of my comrades climbed to the top of Nevado de Chañi about 6100 metres in Puna de Jujuy.

Two ascents were made, the first by Count Eric von Rosen, the second by Dr. R. Fries, Mr. G. von Hofsten and Mr. Wensceslao Mercado. Von Rosen ascended quite near to the top, the others reached it. The summit is of granite; on the north-west side the rock is sandstone.

Dr. Fries made botanical collections. On the top he found lichens. The microscopical life of the snow was poor. The snow line was about 5600 metres. On the side of the mountain there are remains of old houses. On the top there are small walls, and there Hofsten and Fries found pieces of pottery, a little green stone worked by man, a depot of wood of cactus, tola, &c. The walls were built in two small squares with one side open. One of the pieces of pottery was painted with a wedge-shaped (kilformigt) ornament, quite similar to ornaments found by Count von Rosen on pottery from Ojo de Agua, a pre-Columbian "pueblo" in the Quebrada del Toro, some miles to the south. The wood was found both inside and outside of the walls and very well preserved; probably this may be explained from the fact that at this height there are no, or few, microbes. Also in the Puna about 3500 metres above the sea in the pre-Columbian grave-fields, there are still preserved pieces of clothes, skin, instruments of wood, &c.

It seems to me probable that these small walls on the top of the Chañi are the remains of an old sacrifice or signal place from pre-Columbian time. ERLAND NORDENSKIÖLD.

Dalbyo, August 14.

Radiant Point of the Perseids.

YESTERDAY morning, August 11, I watched the northern sky for shooting stars from a place near Baddeck, Nova Scotia, from 0h. 30m. to 2h. 15m. (Atlantic time). During this period I observed forty-nine meteors—mostly faint—forty-one of which appeared to radiate from the constellation Perseus.

While trying to locate the radiant point, I noticed a speck of light flash out in Perseus, which died away without apparent change of position, as though a third-magnitude star had suddenly appeared and disappeared. This was probably due to a meteor advancing directly in the line of sight, in which case the location of the luminous point perceived may be of importance to astronomers, as an indication of the radiant point of the Perseids.

The right ascension was about 2h. 35m., declination $+56°$, as nearly as I can make out from a star chart. I may say frankly, however, that I am not accustomed to make observations of astronomical positions. I can point out the exact position in the sky, and would be very glad if some of my astronomical friends would care to verify the R.A. and Decl.

I may add that the paths of most of the Perseids observed seemed to intersect at or near the point where the stationary meteor appeared. ALEXANDER GRAHAM BELL.

Baddeck, N.S., August 12.

Earth Surface Vibrations.

IN NATURE for August 14, Mr. Charles Stewart writes from the Cape stating that exceptionally rapid barometric variations took place there on the morning of May 28. Mr. Hill states in the same number of NATURE that on the morning of May 8, Mr. Ferdinand Clerc, at St. Pierre, "observed the needle of a large aneroid barometer pulsating violently."

The two similar barometric movements at different places suggest that the air disturbances at St. Pierre did not cause the barometric movement there.

Mr. Stewart assumes there was an earthquake at the Cape for the reasons he gives. But the Royal Observatory showed no record of any seismic disturbance.

If the earth movement took place at the Cape as an absolutely *perpendicular* vibration, would the seismograph have recorded it?

Can sudden and abnormal change in atmospheric pressure cause volcanic or other disturbance on the earth?

August 19. F. C. CONSTABLE.

IN NATURE, August 14, p. 371, it is stated that "at 7 o'clock on the morning of May 8, Mr. Ferdinand Clerc observed the needle of a large aneroid barometer pulsating violently." Above this there is, however, another note which says that "nothing unusual was observed in the barometer." But even supposing barometric perturbations to have taken place on May 8 in St. Pierre, what connection could these have had with phenomena which happened twenty days later at the Cape of Good Hope?

The Milne horizontal pendulum installed at this latter place will record disturbances originating at its antipodes, but will not respond to the rapid elastic vibrations of local shocks. You may hear seismic sounds, windows and doors may rattle, but the instrument in question will remain at rest.

The movement of an earth particle at the time of an earthquake is in all azimuths and at varying angles with the horizon. A strictly perpendicular movement seems an impossibility.

Abnormal changes in atmospheric pressure may act on a region in a state of excessive seismic or volcanic strain much in the same way as the last straw is said to act upon the camel's back; the relationship, however, is far from being pronounced. This and other questions referred to by Mr. Constable are discussed in the volumes on "Seismology" and "Earthquakes" published in the International Scientific Series. J. M.

August 26.

Larva Stage of Heliocopris Isidis.

IN the month of March last, I discovered at a depth of a few cm., among the roots of the tree *Albizzia lebbek*, several large balls of earth, varying in diameter from 5·0 to 8·5 cm. These on being broken open were found to be hollow spheres, the thickness of the wall being about 1·5 cm. This wall was composed of concentric layers of mud and bits of vegetable matter mixed, having the composition and appearance of native unburnt bricks.

Inside the sphere was a coleopterous larva about 2·0 cm. in diameter at its thickest part, about 9·0 cm. in length measured along the dorsal line, and about half that length measured along the ventral line; the larva lay on its side and assumed a curved position. A few days ago, an imago of *Heliocopris isidis* emerged from one of the balls by boring a hole in the roof of its cell just large enough for it to pass through.

If any of these facts are new in the life-history of this beetle, they might interest your readers. FRED. FLETCHER.

School of Agriculture, Ghizeh, Egypt, August 14.

THE LAVA-LAKE OF KILAUEA.

THE recent destructive eruption in Martinique has revived interest in the question of the causes of volcanic action. Only lately have I become sensible of the peculiar value of some observations of my own as evidence of the *primary* force which impels the ascent of lava from its interior habitat, as distinguished from the explosive violence caused by steam generated by the encounter of the ascending lava with ocean and other surface waters.

I have long believed the primary force to reside in the expansion of the gases originally occluded in the magma, ever since its first condensation from the nebula. Whenever released from solidifying pressure by disturbances of the superincumbent crust, the intensely hot magma bursts into a viscid foam and pushes upwards. In a quiet volcano like our Kilauea, meeting no water to generate explosive steam, the lava wells up continuously and steadily in a comparatively gentle fountain, which displays effervescence only on the surface.

In support of this opinion I beg to offer positive evidence contained in certain facts observed by myself in Kilauea during April 8–14, 1892, and on August 28, 1894. The volcano had been in very steady and uniform action for nearly two years before the earlier date, and so continued until a short time after the latter date, or nearly five years in all of a quiet, continuous and rather copious welling up of lava, wholly unattended by any explosive action.

On the earlier date I carefully observed the then existing lava-lake during six successive days. This lake occupied the centre of the inner crater, called Hale-a-mau-mau, or Fern-hut. The main crater called Kilauea is nine miles in circumference, averaging 400 feet in depth, and rather unevenly floored with recent lava. South-west of the centre is the inner pit of Hale-a-mau-mau. This pit was at that time nearly circular

FIG. 1.—Fire-lake as seen in 1891–2.

and 2400 feet in diameter, with vertical sides averaging 150 feet down to the talus. Before the welling up of lava began in 1890, the pit had been about 700 feet deep. In two years the lava had risen 400 feet, and stood within 300 feet of the rim and main floor.

A lake of liquid lava, covered by a thin, spongy film, occupied the centre of the pit. This lake was nearly circular, averaging 850 feet in diameter. It was bordered by a low dyke, which partially restrained its frequent overflows. Outside of the dyke, freshly congealed lava sloped away to the talus. By day the crust-film was grey to the eye, but by night a deep red. It was traversed by numerous fissures of white fire. During the whole time three fountains of lava were welling up with somewhat regular intermittence, and three smaller ones at irregular intervals. There was no explosive action whatever.

The largest fountain was about 120 feet south-east of the centre of the lake. It played with great regularity about three times in a minute, rising in a round billow 25 feet high and 50 feet in diameter, bursting at the top and falling back to level, its discharge moving in a broad stream towards the centre of the lake. The fling of spray from its summit rose to 40 or 50 feet above the level.

West of this central fountain were two others of very different character, being more spasmodic in activity, but never long quiet. Occasionally they would unite their forces for half an hour at a time, forming a stationary line of 130 feet of spraying billow much like a surf-comber with flying spray. This stationary surf-wave was 15 feet high, incessantly flinging its spray 10 feet higher along its whole length. In the night, the effect of these fountains was extremely brilliant and was attended by loud metallic crashing.

The other three fountains were smaller, near the borders of the lake, and often quiet for hours together.

During the thirty months' interval between my two visits, the gradual elevation of the fire-lake continued quite uniformly, as attested by occasional photographs. By its frequent overflows it had built itself up to a height of fully 50 feet above the previous main floor of Kilauea, so that it formed an extremely low truncated cone, surmounted by the level lake, to the edge of which visitors daily approached.

About March, 1894, a recession began, which ended in a final collapse of activity. The lake soon sank some hundreds of feet, carrying with it the sides of a circular pit, about 1400 feet in diameter, and central to the original 2400-foot pit. When I saw it in the following September, the fire-lake was not less than 500 feet below the rim. During the evening, masses of rock frequently crashed in, driving heavy surges of fire far up the talus. There was a good deal of steam-cloud slowly rising, charged with sulphur. During my previous visit, all vapour had seemed to be absent, and I made the circuit of the pit without encountering sulphur. Subsequent photographs had also indicated the absence of vapour from the lake.

FIG. 2.—Fire-lake as seen in 1892-3. Lake gradually rose so as to overtop the rim of the pit, more than 50 feet in 1894, but all the time keeping its position and limits.

I now have to add an important observation. To my great surprise, at this last visit, I perceived that the three fountains above described were in full activity and in the same relative position as before, although during the thirty months the level of the lake had risen 350 feet and had then fallen 500 feet. By what system of supply-ducts such fountains had been so long maintained was a mystery concealed in the fire-depths. But the fact of a marvellous steadiness and uniformity of action was obvious. For a long period a uniform and gentle outpour of effervescence had been maintained. It had persisted for two years and a half, throughout all the immense changes.

I submit as the unavoidable conclusion that the source of supply for this five years' outpour of gently effervescing lava was in an interior magma which itself contained the impelling force in its own originally occluded gases. For its activity this source was wholly independent of any encounter with water to generate steam. Expanding steam evidently had no part in that steady, quiet, persistent activity in the fire-lake of Kilauea.

I would add that the exceptionally quiet and uniform activity of Kilauea seems to render it one of the most important of all volcanoes for study. I regret to say that since the collapse nearly eight years ago no lava has appeared in the crater, except a small quantity last June, which has again gone out of sight.

Having seen no European notice of the fact, I would report that twelve days after the Martinique eruption very vivid afterglows appeared here, about as bright as those seen here after the first two weeks of the Krakatoa glows in September, 1883. They have not yet wholly disappeared. The solar corona, or "Bishop's Ring," is still conspicuous. It is worth stating that the Krakatoa glows reached Honolulu in ten days, coming twice the distance of the Martinique glows in twelve days.

S. E. BISHOP.

Honolulu, July 31.

THE INFLUENCE OF EDUCATION UPON TRADE AND INDUSTRY.

A SHORT time ago the Technical Education Board of the London County Council appointed a sub-committee to report upon the "application of science to industry." The witnesses called before the committee were leaders of science and employers in various branches of industry. Dealing first with the loss of industries to the country, during the last twenty or thirty years, the committee points out that all the witnesses were practically agreed in considering the loss sustained to be due to deficiencies of our educational system. It is not so much the training of the workmen which is at fault; they even consider that the opportunities open to the London workman for obtaining technical education are superior to those enjoyed by workmen abroad. It is the want of highly trained men of science who are able to undertake research work. Prof. Dewar says he knows of no firm in England where chemists are employed in research work, while in Germany a large firm will employ a number of men for research only, who will have no connection with the business or managerial part of the works.

The causes which have operated to keep manufacturers from taking highly trained men into their works are twofold. In the first place, generally speaking, the men who have been employed as scientific experts have had a wholly inadequate training, but have often the idea, as Mr. Beilby says, that they have "nothing to learn and everything to teach." In the second place, the manufacturer is often afraid that they may learn something. He may be willing to take all they can give him, but he will not let them learn the details of the process which he desires to have improved—details which are not to be found in text-books. There is also the lack of scientific training of the manufacturers themselves, and their consequent inability to recognise the importance of scientific assistance.

With reference to our secondary education, Prof. G.

Lunge observes that in our grammar schools the faculty of observation is too little developed, and that mathematics, drawing and modern languages should be more thoroughly taught. "At present there is no time for this, because far too much time and interest are devoted to athletics. The idea that secondary education should mainly aim at breeding manly characters is very fine, but the hardly veiled contempt of positive knowledge which this implies causes much mischief, and this is, of course, much worse if you substitute 'gentlemanly' for 'manly.'" The committee is convinced that scientific industries have suffered, not only through defects in higher scientific education, but to an even greater extent through defects in general secondary education. Mr. Levinstein, in his presidential address to the Society of Chemical Industry at Liverpool, also refers to our want of a sound system of secondary education; he considers that our primary education is fairly good, but what we require is "*general non-specialised secondary education.*" Those engaged in the educational profession must surely have had it forced upon them that the crying need of the country is specialisation; but it is useless. and worse than useless, to attempt to specialise without first having the sound foundation of a thorough general education.

Dr. Merz thinks that science teachers in secondary and public schools are not of a sufficiently high standard as compared with the teachers abroad. They have too little time for improving their knowledge by further study, the result being that they soon become disciplinarians only instead of men of science. Our teachers often seem unable to instil the love of science into their students, who lack the enthusiasm which exists abroad, and may almost be compared to the tradition which is found in our public school life here. How often one hears a graduate say, "Ah! that's finished; I ground up science for my degree, but I shall drop it now." To such men the degree is a qualification and that is all.

In referring to the London polytechnics, the committee recognises the difficulties under which the heads of departments labour if they desire to carry on research. They are understaffed and underpaid, and almost the whole of their time is taken up in teaching or in superintending the teaching of all branches of their subject. It might here be pointed out that in many cases the governors of the institutes, with the exception of those appointed by the Technical Education Board, have absolutely no idea what research means, and strongly object to chemists and others taking up expert work whereby they would obtain an insight into the technical side of their subject, which otherwise it is almost impossible for them to do.

A generation ago the bulk of the manufacture of fine glass for scientific and optical purposes was in English hands. Now it is almost entirely in the hands of Germans. "German chemists have succeeded in introducing such modifications in the manufacture of optical glass that opticians have been enabled to place on the market lenses approaching more closely to mathematical perfection than any previously manufactured in this country." Mr. Conrad Beck says, "there is no place in the whole of England where a man can learn optics in a way that is of any use to him for practical application to optical instrument making. . . . It is a positive fact that if I desire to employ a mathematician to work out my lenses, I cannot find any ready-made man in England." The German Government has not only endowed institutes where optics, among other subjects, is taught in a practical way, but has granted large sums of money "by which costly experiments on a manufacturing scale have been rendered possible."

Mr. Levinstein's presidential address to the Society of Chemical Industry has already been mentioned, and perhaps a short notice of some of the points in it may be of nterest.

In directing attention to the unsatisfactory condition of our trade, he points out that in 1890 our total exports amounted to 328 million pounds. The average amount during the decade 1891–1900 was only 300 millions. That is to say, during these ten years we exported 280 million pounds' worth of goods less than we should have done if the figures for 1890 had been maintained. With Germany it is otherwise; in 1890 the total exports amounted to 3409 million marks, while the average for 1891–1900 was 3688 million marks. Germany has gone forward, we have gone back; this can hardly be called satisfactory. Mr. Levinstein suggests the following as some of the reasons why Germany has advanced so markedly:—

(1) Superior economy, thoroughness, *attention to detail.*

(2) The possession of a far larger number of thoroughly and systematically trained men than any other country (not men only trained technically, but with a thorough *general* training).

(3) A close alliance of legislation and of science with the interests of trade and industry—a result no doubt indirectly due to the high average of general education and training.

(4) A national system of railways and canals, with a scale of internal and external freights averaging less than one-third of our own.

(5) Cheaper skilled labour, *with longer hours than our own.*[1]

(6) A large supply of unskilled labourers, trained to habits of punctuality and discipline through a system of universal military service.

(7) Protective tariffs.

(8) A system of patent laws which takes the interests of the public as well as those of the inventor into consideration.

Some of these conditions obviously could not be introduced into this country, but Mr. Levinstein suggests the following four measures which he considers require immediate attention:—

(*a*) The appointment of a competent and expert Minister of Commerce.

(*b*) The nationalisation and extension of our canals and waterways.

(*c*) A measure for greatly extending and improving our secondary education.

(*d*) A sensible reform of our patent laws.

It does seem an anomaly that a commercial empire such as ours should be without a Minister of Commerce. The Board of Trade is so tied up with red tape and so steeped in routine that deputations upon trade and commerce often receive but scant attention, and have to be content with hazy assurances of good will which are often forgotten almost as soon as uttered.

Mr. Levinstein pays considerable attention to the question of freights. In France and Germany, the combined network of railways and canals enables merchandise to be carried at extremely low rates. Undoubtedly our railway companies might learn a good deal from America as to the handling and haulage of goods, by which means very considerable savings in the cost of transport could be made. But owing to the enormous cost of construction and over-capitalisation of our railways, even if all possible improvements were introduced and the boards of directors were business men and not appointed because of their social position, we could not compete on level terms with other nations. But how about our 4000 miles of canals? For years they have hardly been used at all, and many of them have become antiquated and are almost, if not quite, ruined. In contradistinction to our want of forethought, France, Belgium and Germany have been continually increasing and improving their canal system, and America, that land of restless energy, is building canals. Before the opening of the Erie Canal the cost of moving one ton of freight from Buffalo to Albany was 100 dollars; on the opening of the canal this immediately

[1] The tendency here seems to be a general shortening of hours and extra holidays to watch *others* playing games.

fell to 10 dollars. At present the cost of moving merchandise by canal from Buffalo to New York, a distance of 500 miles, does not, on the average, exceed one dollar, or four shillings per ton.

European States are devoting millions of money annually to the construction of canals and canalised rivers, with the result that it costs less to-day to bring sugar from Hungary, thousands of miles across Europe, to London than to carry the same sugar on our own railways from London to Manchester. Goods which can be carried from Hamburg to Berlin, a distance of 174 miles, at four shillings per ton cost eight shillings and fourpence per ton from Manchester to Liverpool, a dis-of 30 miles. Cattle can be sent at less cost from Chicago to Liverpool (about 4000 miles) than from Northumberland to Liverpool. It costs more to send one ton of goods from London to the west of Ireland than from London to Japan. Denmark can send her dairy and farm produce to London at less cost for transport than can the English farmer living only 30 miles away in the home counties.

Mr. Levinstein calls for a reform of the patent laws. He attributes, as do many of the witnesses examined by the committee of the Technical Education Board, much of the success of the German manufacturer to the excellent and protective patent laws, which have been in operation since 1876. Yet though our patent laws leave very much to be desired, they do not directly, as Prof. Meldola points out, prevent discovery or originality. Indirectly they may do so, because if a man feels that his invention is not properly protected, he may give up working in disgust. In order that a patent may be valid in Germany, it is necessary that the article patented should be manufactured in Germany. We have no similar provision. It pays an inventor to manufacture in Germany and export to England better than to build extra works here, where British labour would be employed.

Admitting, however, that our patent laws are bad, our manufacturers narrow-minded and unscientific and our business methods lacking in enterprise, and that therefore we are, if not absolutely falling behind, barely holding our own in the markets of the world, we always come back to the fact, if we will but admit it, that all these causes may directly or indirectly be traced to our educational system or want of system.

The report of the Technical Education Board is so valuable that I should like to suggest that the County Council publish a digest of it in pamphlet form and circulate it among manufacturers in London. This may seem a rather large order, but how otherwise are these men, upon whom so much depends, to be reached?

F. Mollwo Perkin.

BIRD-PHOTOGRAPHY IN THE GARDEN.[1]

ALTHOUGH he disclaims the title of naturalist and states that he knows nothing of photography, the author has contrived to produce a very entertaining little work, illustrated by reproductions from photographs which we have seldom seen equalled and rarely surpassed. They are, in fact—especially the full-page plates—ideal representations of the birds they portray, and ought to tempt the amateur photographer to try to do likewise—if he can. The object of the volume, like so many others at the present day, is to show the outdoor naturalist and bird-lover how full an insight he can obtain of the life-history and habits of his feathered favourites by portraying them in their natural haunts and surroundings. And with this end in view, he describes in some detail the type of camera and plates best suited for the purpose, and the mode of using them. His main difficulty appears to be to find a "shutter" which shall be sufficiently rapid in action, and at the same time not frighten the bird as it falls.

As the title implies, the author, in place of wandering far afield, has been content with the birds commonly met with in any English country garden, and he shows how much may be learnt that is more or less new even with regard to familiar species. Perhaps he would have been better advised had he refrained from saying that our knowledge of bird-anatomy is such that work is no longer needed in that branch of ornithology. Indeed, it is a great pity that field-naturalists and museum-workers are constantly in the habit of belittling one another's efforts; each has his appointed place, and the work of the one cannot be completed without that of the other.

The author restricts himself to ten species, five of which are tits, and he has something interesting to say about each. If we were asked to select the two best illustrations in a work in which all the pictures are charming, we should choose the page-plates of the pied flycatcher and redbreast. We reproduce one of the text-figures.

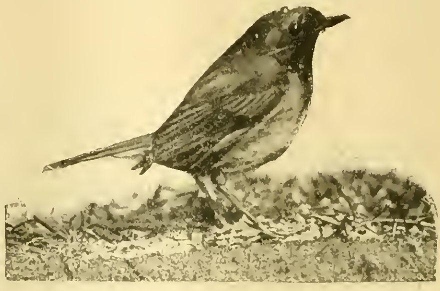

Fig. 1.—Robin Pausing at Food. (From "Birds in the Garden.")

[1] "Birds in the Garden." By G. Sharp. Pp. xi + 190; illustrated. (London: J. M. Dent and Co., 1902.)

A NEW THEORY OF THE TIDES OF TERRESTRIAL OCEANS.

MR. ROLLIN HARRIS has done so much good work in preparing his "Manual of Tides" for the United States Coast Survey that it is an ungrateful task to find oneself constrained to criticise adversely his recently published part iv. A of that treatise.[1]

I shall pass over many points of interest which occur in the earlier portions of the book, because the discussion of them is apparently designed to lead up to a new theory of oceanic tides. That theory, to which I shall confine my attention, depends on a proposition that it is possible to dissect our oceans into a number of basins in which the oscillations are virtually independent of one another and are almost unaffected by the diurnal rotation of the earth.

We may, then, pass at once to chapter vi., where Mr. Harris considers forced oscillations in tanks, as impeded by friction. The waves are treated as long waves in which the water in any vertical slice always remains vertical, and the friction is assumed to be proportional to the velocity of the slice. These assumptions are open to criticism, but I will follow Mr. Harris in supposing that

[1] Reports of the U.S. Coast Survey. Parts i., ii., Appendices 8, 9, Report for 1897. Part iii., Appendix 7, Report for 1894. Part iv. A., Appendix 7, Report for 1900.

the physical conditions are adequately represented in this way.

He desires to find a solution when the period of the external disturbing force is the same as that of a free standing oscillation of the type of a seiche in a lake. For a seiche with a single central node the length of the tank must be equal to half the distance traversed by a long wave in the period of the external force. Thus the size of the tank is determined by the period of the external force and by the depth of the water. In the detailed treatment of the problem the depth is supposed to be uniform. Mr. Harris writes his equation of motion in the form of an equation of virtual work; he reverses the forces of inertia, adds them to the impressed forces and equates the virtual work to zero. Lagrange made the displacements arbitrary, and thus his equation of virtual work was exactly equivalent to as many differential equations of motion as there were variables; but Mr. Harris takes the displacements as proportional to the actual displacements per unit time and obtains a single equation. This is permissible, but the result cannot be anything but an equation of energy. I am unable to see any advantage in this procedure. He then assumes that the type of oscillation will be the same as in free oscillations, but this is surely a quite unwarrantable assumption. If the periodic forces have the same period as the free oscillation the oscillations will be large, but the type will in general be different. Does not this error vitiate his whole treatment of the problem? However, let us proceed. The type and period being the same as those of a free oscillation in the absence of friction, the periodic sustaining forces must exactly balance the frictions, and the frictional forces are proportional to the velocities. Now the motion being of the same type as in a free oscillation, the displacements are all simple harmonic functions of the time, and at any instant are all in the same phase. Hence the frictional forces, and therefore also the sustaining forces, are all in a phase differing from that of the displacements by a quarter period. Thus all the sustaining forces vanish at the instant when the displacement is a maximum, and we get nothing out of the equation of virtual work but what was put into it by dubious assumptions.[1]

As a result of this discussion the following rule (p. 621) is given:—

"Project the force arrow" (of a number of tidal-force diagrams giving the direction and magnitude of the forces at various parts of the basin at successive hours) "belonging to the assumed time in each diagram upon the line of motion passing through it; the aggregate of the elementary masses, each multiplied by the intensity of the tidal force in the direction of the displacement, and again by a quantity proportional to the value of the maximum displacement (since the oscillation is harmonic), must be zero at the time of high and low water. The algebraic sum of these products for any given hour should be plotted as an ordinate at that hour. Where the curve thus constructed crosses the time axis denotes the time of high and low water."

Besides the objection to the proposition raised above in the case of the canal of uniform depth with synchronous disturbing force, I fail to see any adequate consideration of the variability of depth, of the absence of synchronism in the component disturbing force in the direction of the canal, or of the effects of the component transverse to the canal.

But even if it were possible to assent to this rule, it appears to me that there are other still more doubtful assumptions. On p. 624 we read:—

"Considering the actual distribution of land and water, a few computations upon hypothetical cases will suffice to convince one that as a rule the ocean tides, as we know them, are so great that they can be produced only by successive actions of the tidal forces upon oscillatory systems, each having, as free period, approximately the period of the forces, and each perfect enough to preserve the general character of its motion during several such periods were the forces to cease their action. This greatly simplifies matters. . . ." Undoubtedly the simplification is great, but is it true?

Then later:—"The paths of the particles being practically fixed and determined by the boundary conditions, it becomes possible to disregard the forces arising from the earth's rotation."

Now Lord Kelvin has concluded that "the oscillations of water in a rotating rectangular trough are not of the simple harmonic type in respect to form, and the problem of finding them remains unsolved" (*Phil. Mag.*, vol. x., 1880, p. 113). He has, however, solved the case of a rotating endless canal with straight sides, and adduces his results as probably dominating some remarkable characteristics of the tides of the English Channel. It seems to follow that either Lord Kelvin or Mr. Harris is wrong.

I gather that the free period of oscillation in the several basins into which the ocean is partitioned is the same as that of the tidal force. Now it is surely profoundly improbable that any large portion of our curiously shaped oceans should possess even approximately the critical free period, yet unless this is so the theory seems to be inapplicable. Finally, I think that the process of partition should receive an elaborate and critical discussion as to each basin; but I do not find that this is given in the book.

I can, in conclusion, only express a hope that I am not doing an injustice to Mr. Harris in dissenting so absolutely from his views. No one would have welcomed more warmly than I a new clue to our treatment of this difficult problem. I venture to express my admiration at the courage of the attempt, and although, as I think, it is a failure, yet it may inspire others to more successful attacks. G. H. Darwin.

[1] A considerable portion of this criticism is due to Prof. Love, with whom I have had the advantage of discussing the matter. He points out, further, that Mr. Harris's equation (308), p. 619, which forms the key-note of the whole, is really identically satisfied by the assumptions.

NOTES.

The hundredth anniversary of the birth of Abel, the great Norwegian geometrician, is on the point of being celebrated at Christiania. Representative men of science from many countries are expected to be present. The interest which His Majesty King Oscar II. has manifested in this centenary celebration is another proof of his continued sympathy with mathematical work and scientific research generally. It is announced that the Paris Academy of Sciences will be represented by M. Darboux and the Paris University by M. Émile Picard.

It is announced in *Science* that at a recent meeting of the corporation of the Marine Biological Laboratory at Woods Holl it was voted to transfer the Laboratory and its equipment to the Carnegie Institution. This action was taken after it had been stated to the members of the corporation that the executive committee of the Carnegie Institution would recommend to the trustees that the Laboratory should be accepted, that its debts should be paid, that new buildings should be erected, that 20,000 dollars a year should be allowed for maintenance and that the scientific management should rest as heretofore with the naturalists of the United States.

The Cape Town correspondent of the *Times* states that great interest is being manifested there in the suggested visit of the British Association in 1905. As a preliminary measure, free passes on all the South African railways are promised for the

delegates, while the Colonial Governments will contribute 7000*l.* towards the expenses of the voyage and of the stay in South Africa.

A REUTER message from Barcelona, dated August 27, states that a severe storm has passed over Felanitz, Majorca, causing great damage in the town and district. The storm was accompanied by a downpour of rain. Several places were flooded and many houses were destroyed by lightning, by which several persons were killed. A south-easterly gale of exceptional violence was experienced on the southern coast of Cape Colony during Sunday evening, August 31, and Monday, September 1, causing much damage and loss of life.

THE following reports of eruptions and earthquakes have appeared during the past week :—*August* 27. A telegram from General Chaffee, the Commander-in-Chief in the Philippines, to the U.S. War Department, states that a series of earthquakes has occurred in Lake Linao country, in the Moro section of the island of Mindanao. The rivers and mountains have been considerably disturbed. Four hundred shocks have been felt since August 21. *August* 26, *St. Thomas.* A despatch received from Dominica at 6 p.m. reports that since two o'clock rumbling noises in quick succession have been heard from the southward, and that there is every indication that Mont Pelée is in violent eruption. *August* 30. A violent eruption of Mont Pelée destroyed Morne Rouge and Ajoupa Bouillon. About 1000 persons were killed and several hundred injured. A wave caused much damage at Carbet. A violent earthquake shock was felt at Carupano, on the coast of Venezuela, at 9 p.m. The disturbance was accompanied by a noise which was heard along the whole shore of the Caribbean Sea. *September* 1. The vessel which was sent to Tori Shima to report on the results of the volcanic disaster in that island in the middle of August has returned to Yokohama, and reports that Tori Shima is in a state of utter ruin. More than 150 lives were lost in the eruption, no one being left alive on the island.—A telegram from Castries states that Mont Pelée has been in constant eruption since August 15. There was an enormous fall of ashes on the night of August 25, and a very severe eruption on the night of August 28. Three eruptions occurred on the night of August 30, and it was impossible to reach St. Pierre from the sea.

AT the annual congress of the Royal Institute of Public Health, which concluded its sittings at Exeter last week under the presidency of the Earl of Iddesleigh, the necessity for teaching the principles of public health in rural districts was strongly urged, and the creation of a "Ministry of Public Health" advocated. Prof. Sims Woodhead directed attention to the need for further funds for the investigation of diseases such as cancer and tuberculosis, and pointed out what a good investment such expenditure would be as regards the national welfare. In the veterinary section, the deplorable condition of town and country stables and country cow-sheds and piggeries was alluded to by Mr. Eaton Jones in a paper on the "Veterinary Supervision of Domesticated Animals," and the meeting passed a resolution advocating the abolition of private slaughter houses, the appointment of veterinary inspectors of all animals intended for food, the inspection of dairies and cow-sheds, and the providing of suitable provision for the disposal of the carcases of animals unfit for food. At a final meeting, Mr. Windley attempted to defend the course pursued by Leicester in its neglect of vaccination, and Dr. Millard suggested that the danger of the spread of small-pox supposed to arise from the presence of a large unvaccinated element in a community had been somewhat overrated. Prof. Smith pointed out that even in Leicester the hospital staff had been vaccinated, and that in the London small-pox hospitals the staffs were subjected to compulsory vaccination and not a single case of small-pox had occurred among them; he believed that no one would attempt to establish a small-pox hospital and to officer it with an unvaccinated staff. The formation of a national water board, the new pharmacy bill and the construction of sanatoria for consumptives were the subjects of discussion in various sections.

PROF. VIRCHOW, who has been lying extremely ill at Harzburg, has been moved to Berlin, where he arrived on Saturday last. His strength is said to be unmistakably failing.

LORD CURZON, the Viceroy of India, has ordered the heads of the Veterinary, Survey, Forest, Meteorological, Geological, Agricultural and Botanical Departments of India to form a board of economic inquiry, which shall meet twice annually to formulate a programme and to review past work. The board is also to act as an advisory committee to the Government. The Royal Society has promised its assistance.

FROM the *Daily Mail* we learn that as a result of the last anti-tuberculosis conference held at Berlin a special organisation called the International Central Committee for the Prevention of Tuberculosis has now been established. The first meeting will be held under the patronage of the German Empress on her birthday, October 22, under the presidency of Prof. Von Leyden. Many prominent physicians from various countries will also be present. The organisation has already 120 members.

THE sixth annual week's fungus foray of the British Mycological Society will be held at Hereford, from Monday to Saturday, September 22–27.

THE following papers will be read in the Section of Physiology at the British Association in Belfast, in addition to those already mentioned (p. 377):—Prof. Symington and Dr. Cecil Shaw will show Edinger's drawing apparatus for higher magnifications and stronger light; the functions of the rods and cones of the retina, Mr. F. W. Edridge-Green; on the movements and innervation of the stomach, Dr. Page May; a new method for demonstrating cholohæmatin in ox-bile, Dr. W. A. Osborne.

THE *Patent Office Gazette* reports that patents on eleven different parts of wireless telegraphic apparatus have been granted by the U.S. Patent Office to Prof. Reginald A. Fessenden. Among the patents are included a device for signalling by magnetic waves, a current-actuated wave-responsive device, and also a conductor for wireless telegraphy apparatus.

A REUTER message from Ferrol states that on Friday last Mr. Marconi received a number of Spanish telegraphists on board the Italian cruiser *Carlo Alberto.* In the course of conversation, he stated that he was in daily communication with a receiving station near Plymouth and by this means had received news of the arrival of the King of Italy in Berlin. Referring to the prevention of interference of simultaneous messages, Mr. Marconi said that he was able recently to keep constantly in communication with England at the same time that men-of-war were communicating with each other and with the stations situated in the regions of the Hertzian waves.

A NEW York contemporary states that the De Forest system of wireless telegraphy has now been in practical operation for some months between New York and Staten Island. In this system, an anticoherer of the electrolytic type is employed, its chief advantage lying in the fact that it requires no tapping back; a telephone is used in conjunction with this instrument, and the Morse signals are read by ear. The induction coil is eliminated from the sending apparatus, the spark being produced

by a pressure of 50,000 volts obtained by transforming up from the street mains. It is said that a speed of 25 to 30 words a minute is easily maintained. An instance is quoted of two messages having been read at the same time from the same receiver, one coming from an "outside" source, probably a Marconi station. This seems a doubtful recommendation for the system, and shows that the time can not be so very far distant when some consolidation of all the competing systems will be essential. It is to be hoped that this may result, not merely in the survival of the fittest, but in the evolution of a system possessing all the special advantages of the various competitors.

A NEWFOUNDLAND correspondent contributes a lucid and interesting article on "This Year's Arctic Work" to a recent issue of the *Times*. The preparations made for Baldwin's expedition northward from Franz Josef land, which has ended unaccountably in failure, are described with considerable detail, and the unusual completeness of Baldwin's equipment makes the return without substantial achievement all the more remarkable, especially in comparison with the results of the Duke of the Abruzzi's expedition. A short account of Peary's twelve years of Arctic work brings the extraordinary sufferings of that indefatigable explorer into strong relief, and the prospects of his success and safe return this year from what is to be his last Arctic journey are discussed. The safety of the expedition led by Sverdrup, captain of Nansen's *Fram*, which started from Jones Sound in 1899 to explore the vast unknown area beyond the Parry Islands and has not been heard of since, is already doubtful, and unless it returns this summer its position must be one of extreme peril, as it was only provisioned for three years. Should Peary and Sverdrup return safely this season, the Arctic regions will next spring be without a single investigator, a circumstance that has not occurred for more than fifteen years.

WE learn from the *Journal* of the Society of Arts that the Association of German Machinery Engineers of Berlin has offered prizes of 5000, 3000 and 2000 marks (250*l*., 150*l*. and 100*l*.) for a constructive tracing of a locomotive able to pull a train of 180 tons in weight, on a level roadway, at a speed of 120 kilometres per hour (74·5 miles) for a continuous run of at least three miles, the highest rate of speed not to exceed 150 kilometres (93·2 miles) per hour. The close of the competition is fixed for December 1, 1902. Any further particulars may be obtained by applying to the secretary of the above association, Herr Geheimer Kommissionrath, F. C. Glaser, Lindenstrasse 80I., Berlin.

OUR American contemporary *Science* protests strongly against the appointment of Captain Colby M. Chester, a naval officer without special knowledge of astronomy, as superintendent of the U.S. Naval Observatory. The institution is regarded as the national observatory of the United States, and the opinion is expressed that an astronomer should be at its head instead of a naval officer. Our contemporary adds: "The institution has no rational purpose of existence except a desire on the part of the American people that our nation shall, in its public capacity, do its full share in the promotion of those branches of astronomy which have to be pursued under public auspices. The leading position which our country has taken in the extraordinary development of astronomic science during our generation can alone justify the unparalleled expenditure of our Government upon its observatory. The results of this expenditure through the ten years since the completion of the new observatory should have been its general recognition as the leading observatory of the world in at least some important field of the sciences. With its great advantages over old-fashioned Greenwich and Paris, it should have left both these institutions in the rear."

M. DE FONVIELLE informs us that M. Camille Pelletan, Minister of the French Marine and of the Colonies, has placed the *Epée*, a torpedo destroyer, 306 tons, 62 men, at the disposal of Comte de la Vaulx for purposes of aëronautical manœuvres on the Mediterranean, with a new balloon. It may be remembered that last year Comte de la Vaulx tried to cross the Mediterranean from Toulon with a large balloon made captive by floating pieces of wood. The experiment, although interesting, proved a failure, owing to the wind blowing eastward. This year the experiments are likely to begin from Palavas, a point near the place where, in 1901, the trip ended. The *Epée* is to join the balloon there on September 10. The new balloon will carry in its car a propelling petroleum engine, which, however, will be used only in the second series of manœuvres. On Sunday, August 24, M. Heureux, a young and promising aëronaut, tried on a smaller scale similar performances in the Channel. He proved by an ascent at Dunkerque that a tug-boat can conduct a balloon against a strong wind. The balloon *Alcor* was sent up in the direction of the sea and for same time was lost to view in the clouds; but, after baving run some miles, tbe valve was opened and the balloon descended close to the waves. M. Heureux dropped his cone-anchor and waited until a tug-boat, sent out especially from Dunkerque, threw a rope to the car, by which the balloon was tugged easily and reached Dunkerque fully inflated.

AT the annual meeting of the Société d'Encouragement pour l'Industrie nationale, the president announced the mode of distribution of the grants at the disposal of the Society for research work bearing upon industry. The gold medal of the Society for work which has exercised the greatest influence on French industry is awarded to M. V. Steinlen for his researches on the invention and construction of machine tools, M. Rabate receiving the Parmentier prize for his original studies on the resin industry. Money grants were also given to M. Fremont (3500 fr.) for his work on the testing of metals, to M. Gutton (3000 fr.) for his work on the fragility of materials, to M. C. Brioux (2000 fr.) for his geological and agricultural study of Basse-Bourgogne, to M. C. Urbain (500 fr.) for his work on the acetylacetonates, to M. Guyot (500 fr.) for his researches on colouring matters, and to M. Canovetti (1000 fr.) for his work on air resistance. The total amount of the grants for research made by the Society for the years 1902–1903 is twenty thousand francs. The president expressed the hope that the industries which benefit by this sacrifice will lend assistance in their turn in providing for the commencement of new studies which the Society has not as yet been able to attempt for want of sufficient funds.

ON the occasion of the recent meeting of the members of the British Pharmaceutical Conference at Dundee, the president, Mr. J. C. Druce, summarised in his address the progress of Scottish botany. The review begins with an account of the work of Robert Sibbald, who lived in the latter half of the seventeenth century and compiled the work known as "Scotia Illustrata." After him, the more important systematic botanists referred to are Dr. Lightfoot, the author of "Flora Scotica" (1777), Sir James E. Smith, whose "English Botany" is a standard work, George Don, famous on account of his botanical explorations (1800), Sir W. J. Hooker, who also published a "Flora Scotica" (1821), and Mr. H. C. Watson, to whom we are indebted for the "Cybele Britannica" (1847–1860). The most impressive part of the address is the vivid sketch of George Don, who, humbly born and poorly educated, devoted himself with untiring energy to scientific, more especially botanical, observations, and was the first to explore many Highland districts now famous, but at that time quite unknown. Owing to unfortunate circumstances, many of Don's discoveries have been called into question,

but later investigations tend to re-establish his reputation. There is no doubt that, owing to the fact that he sent out specimens from his garden, and that his references to localities were at times inaccurate, his records are not always trustworthy; on the other hand, some of his doubted specimens have since been re-affirmed, of which Mr. Druce mentions *Salix doniana*, *Triticum alpinum* and *Carex ustulata*. The concluding part of the address furnishes a list of species peculiar to Scotland, and an account of species characteristic of counties or districts.

Now that autumn is approaching, and it is time to be planting bulbs, those growers who require daffodils will be interested in the catalogue issued by Messrs. Barr and Sons. This firm has for a long time made a speciality of these flowers, and offers all varieties, from the inexpensive kinds suitable for planting in woodlands to the select and rare hybrids which require several years to raise from seed.

THE report on the St. Kitts-Nevis Botanic Station, for the year ending March 31 last, states that in August, 1901, an experiment with tobacco was successfully established on half an acre of ground. Plots were also started on four estates, advice and assistance being constantly given to those in charge, and the planters invited to witness each operation in progress. With seed procured from England, another attempt was made to cultivate potatoes, but the results went to show that instead of producing what we know at home as "new" potatoes, the crop when reaped was found to have precisely the flavour and conditions of old potatoes. For the purpose of destroying grasshoppers, an endeavour was made to acclimatise the Barbadoes blackbird. Several consignments of birds were received, but nearly all disappeared, a few being seen only in one or two places where they are regularly fed.

THE *Journal* of the Royal Microscopical Society for June contains an interesting paper, by Mr. C. F. Rousselet, on the genus Synchaeta. Some of the members of this genus are amongst the commonest rotifers inhabiting fresh-water lakes and ponds as well as brackish tide pools and the open sea. Pastor Eichhorn (1761) and F. O. Müller (1786) are probably the earliest authors who have left sketches probably representing species of this genus; but our real knowledge of these rotifers dates from 1831 to 1834, when Prof. Ehrenberg described four species of Synchaeta. Mr. Rousselet now records sixteen different species, of which five are new, viz. *S. kitina* (in fresh water), *S. littoralis* (in brackish water), *S. cecilia*, *S. vorax* and *S. neapolitana* (marine).

A NOTE by Prof. Garbasso, of Turin, contributed to the *Nuovo Cimento*, 5, ii., deals with a phenomenon observed by Prof. Manuelli, viz. the action of sunlight in facilitating the passage of electric sparks, an effect closely resembling, if not identical with, Hertz's phenomenon. Prof. Garbasso has made experiments which show that even diffused sunlight has a considerable effect. In one experiment he counted 24 discharges in 30 seconds in the light as against 8·8 in darkness; in another experiment the numbers were 18·1 and 6·3. The effect of the light seems to last for a certain interval after the illumination is cut off. Experiments were made first with a lens and next with a mirror used for concentrating the rays; and it was also found that when the light was brought to a focus on one of the electrodes, an uninterrupted current was obtained even at distances beyond the sparking distance in the dark, but the effect was greatest when the light fell on the negative pole. This influence of solar light is unaffected by the passage of the light through quartz or Iceland spar, but is destroyed by a few films of mica, a thick glass plate, or a vessel of water or alum solution 4 cm. thick. These results point to the view that the effect of Manuelli is due, not to the presence of ultra-violet rays, but rather to the heating of the electrodes.

Bulletin No. 51 of the U.S. National Museum will be exceedingly useful to working naturalists, since it contains a list of the publications of that institution from the year 1875 to 1900, drawn up by Mr. R. L. Geare.

THE last issue of the *Transactions* of the South African Philosophical Society, comprising pp. 561 to 896 of vol. xii., is entirely devoted to a continuation of the valuable descriptive catalogue of the beetles of South Africa. A very large number of new species as well as some new genera are described in this fasciculus, the diagnoses of which appear to be well and carefully drawn up. We think, however, it would have been better had the dates been added in all cases to the references to previously named genera and species.

Science for August 15 contains a full report of a long address on the history of ichthyology, delivered by Prof. Jordan before the zoological section of the recent meeting of the American Association, held at Pittsburg. Commencing with Aristotle, the lecturer gives a full account of the gradual progress of our knowledge of recent and fossil fishes, in the course of which he allows full credit to the efforts of the earlier workers, especially Artedi, whose list of genera is given at length. The British Museum catalogues of fishes, recent and fossil, receive a large share of commendation. Of one of these the lecturer speaks as follows:—"The chief criticism which one may apply to this work concerns most of the publications of the British Museum. It is the frequent assumption that those species not found in the greatest museum in the world do not really exist at all." We venture to doubt whether this sweeping criticism is deserved. Readers with a knowledge of British fish-literature will not fail to notice that the first appearance of Yarrell's work is misprinted 1859 (in place of 1839) in the report of the address.

In the August (third) number of the *Field Naturalist's Quarterly*, the editor devotes the opening paragraphs to a discussion of the present form of nature-teaching in schools, and the manner in which this may be improved. It is essential that the lessons should be simple and practical, and the author recommends that a child should be encouraged to watch and describe the life-history of a common insect, or the daily development of a flowering plant. Later on in the same number, Mr. R. Haines discusses the difficulties in connection with the establishment of an "Arbor-day" in this country. The main idea of such an institution is that on a certain day each inhabitant of a village or town should plant a tree; and the author very pertinently inquires who is to provide the trees and the land on which they are to be planted, and the kinds of trees to be selected. He might have asked who is to be responsible for the attention and care they will certainly require during the earlier years of their growth.

WE have received from Dr. H. Hergesell the year-book of meteorological observations taken in Alsace and Lorraine during 1898. For Strassburg, hourly or two-hourly readings are published, and the usual observations at ten stations of the second order. Rainfall summaries are given for fifty-eight stations.

THE eighteenth volume of observations made at the Hong Kong Observatory for the year 1901 has been published by Dr. Doberck. The comparison of the daily weather forecasts with the weather subsequently experienced shows, as in previous years, a large amount of success, the sum total (including cases of partial success) reaching 93 per cent. The useful work of collecting observations from ships' logs, for the construction of pilot charts for the eastern seas, has been vigorously continued; the number of entries in 10° squares available for each month of the year save two exceeds twenty thousand. The magnetic and astronomical observations have also been regularly carried on. In the year 1901, the number of transits observed was 3349.

WE have received from Prof. F. Omori the first portion of a memoir on macro-seismic measurement in Tokyo, containing the analysis of the diagrams of 220 earthquakes observed at three places in that city, mostly between September, 1887, and July, 1889. Prof. Omori defines the macro-seismic motion as that part of the earthquake-motion which consists of vibrations the period of which, except in very strong shocks, does not exceed two or three seconds. A discussion of the analysis will be given in the second portion of the memoir.

DURING the past year, we have received the nine parts forming vol. vii. of the *Bollettino* of the Italian Seismological Society for 1901–1902. The description of new instruments or of modifications of old ones is, as usual, a prominent feature of the volume. We have noticed already several of the papers, and need here only call attention to Prof. Mercalli's studies of Vesuvius from July, 1900, to the end of 1901, Prof. Riccò's paper on the central crater of Etna, and the valuable notices of earthquakes recorded in Italy during the year 1900.

THE Home Office has issued the annual report relating to persons employed and accidents at mines and quarries in the United Kingdom in 1901. It is edited by Prof. C. Le Neve Foster, F.R.S., and contains a large amount of interesting information. The total number of persons employed was 933,366. There were 1075 accidents, causing the loss of 1229 lives. Compared with the previous year, there was a decrease of 48 in the number of fatal accidents, but an increase of 52 in the number of lives lost. The general death-rate was 1·348 per 1000, as compared with 1·408, the average for the past ten years. Of the fatal accidents, 43·7 per cent. were due to falls of ground, 11·0 per cent. to explosions, 13·5 per cent. to surface accidents, 7·0 per cent. to shaft accidents, and 24·8 per cent. to miscellaneous accidents underground. The use of coal-cutting machinery does not appear to be making very rapid progress.

THE School of Mines of the University of Wyoming has issued a series of bulletins on petroleum, and of these No. 5 (June) deals with the Newcastle oilfield. Petroleum occurs in the Dakota shales and sandstones near the base of the Cretaceous, and it proves of value for lubricating and for fuel.

AN interesting account of the Darling Downs district in Queensland is given by the Hon. Arthur Morgan (*Proc.* Roy. Geograph. Soc., Australia, vol. xvii.). He dwells especially on the work of Allan Cunningham, who in 1827 discovered the Darling Downs, now regarded as one of the most fertile and healthful tracts, and also as a region of considerable geological interest, for it has yielded remains of remarkable fossil mammalia, gigantic in size compared with the recent representatives.

DR. HENRY WOODWARD contributes to the *Proceedings* of the Bath Natural History and Antiquarian Field Club (vol. x.) an interesting outline of the life of William Smith, the "father of English geology." It is accompanied by a portrait (reproduced from Phillips's "Life of William Smith"), by a photogravure of the bust by Chantry, which stands in St. Peter's Church, Northampton, and by a view of the monument erected by Lord Moreton, at Churchill, in Oxfordshire, the birthplace of Smith.

IN some contributions to South African petrography (*Geol. Mag.*, August), Mr. Frederic P. Mennell, curator of the Rhodesia Museum, refers to the great development of basic lavas and acid plutonic masses. He describes examples of basalt, dolerite, gabbro, syenite, &c., that have been gathered from a wide area in Rhodesia, Bechuanaland and other parts of South Africa. The great granite mass of the Matopos, which forms the backbone of southern Matabeleland, closely resembles the Dartmoor rock, but near Bulawayo it presents appearances of foliation which may be due to movement before complete consolidation.

SOME interesting details relating to the recovery of tin from tin-scrap have recently been published in the *Zeitschrift f. Elektrochemie*. In Germany, several works have been built and operated for carrying out this procedure, the largest of these being that of Goldschmidt, at Essen, where 50–60 tons of tin-scrap are reported to be treated per day. The difficulty of obtaining an adequate supply of raw material has hindered the development of other works, and the anonymous writer of the article we are discussing hints that the supply of tin-scrap is monopolised by one or two of the larger works. The processes used for recovering the tin are based upon the use of the scrap as anode material, in a bath containing sodium chloride and hydrate, or in one containing hydrochloric acid. The advantage of the former is that less iron goes into solution, but against this there is the lower energy efficiency of the process and the more spongy nature of the deposit obtained at the kathode. The failure to produce directly metallic tin is one of the chief difficulties in the operation of both processes, for considerable losses occur in smelting and refining the spongy deposit obtained at the kathode. Under certain conditions, metallic tin can be obtained in the electrolytic bath, and Pfanhauser, in the issue of the *Zeitschrift f. Elektrochemie* for January 16, has stated his opinion that the avoidance of the formation of sponge is simply a question of maintaining the *concentration of the tin salt solution* in the neighbourhood of the kathode. This condition would appear to be difficult to attain in the works treating tin-scrap on an industrial scale, and the problem of producing metallic tin at the kathode is complicated further, by the slow but gradual increase of impurities in the electrolyte. A new works for the treatment of tin-scrap has recently been built at Pfaffstätten, near Vienna, and an electrolytic process for recovering tin from slags is also reported to be in operation at Tostedt, in Germany. In this country we are not aware of any similar works in actual operation, but during 1901 a company was formed with a capital of 10,000*l.* to build and operate a works for the treatment of tin-scrap by a new electrolytic process. A plant for dealing with 50 tons of cuttings per month was to be erected, presumably near London.

MESSRS. WHITTAKER AND CO. will shortly publish a work on galvanic batteries, by Mr. S. R. Bottone. The book will deal with the theory, construction and use of electric batteries, comprising primary, single and double fluid cells, secondary and gas batteries.

MESSRS. NEWTON AND CO. have sent us a copy of a useful catalogue of physical apparatus and accessories manufactured by them. In addition to numerous figures in the text, the catalogue has eight plates containing reproductions of photographs of typical instruments used for demonstrations in the lecture room and practical work in the laboratory. Among the apparatus described, we notice a cyanine prism for showing anomalous dispersion, circular diffraction gratings and photographic gratings, zone plates, new contact breaks, localising instruments for Röntgen ray work, apparatus for wireless telegraphy demonstrations, and for experiments with alternating currents of high tension and high frequency.

WE have just received the annual report of the Government Analyst at Trinidad. The report indicates that in addition to the examination of officially submitted samples, of which more than 2000 were received during the year, a considerable amount of valuable work is being done by the head chemist, Prof. Carmody, by investigation of the mineral deposits of the island. Experiments have also been made at the Government farm on the diurnal variation of cow's milk.

ACCORDING to the report of the principal chemist of the Government Laboratory for the year ending March 31, it appears that during the past twelve months the work of the Customs branch of the Laboratory has more than doubled in magnitude, the increase being due chiefly to the imposition by the Budget of April, 1901, of duties on sugar and cognate substances, and on the numerous articles in the manufacture of which these substances are used. More than 64,000 samples were submitted for test as compared with about 34,000 in the preceding year.

A CAREFUL experimental inquiry regarding the nutritive value of alcohol has recently been carried out in the chemical laboratory of Wesleyan University by Messrs. Atwater and Benedict, a report on which forms the sixth memoir of vol. viii., published by the National Academy of Sciences. The main question studied is the value of alcohol as a fuel in the human body and its comparison in this respect with sugar, starch, fats and other nutrients of ordinary food materials. Collaterally, the question of the effect of alcohol upon the proportions of nutrients digested from the food with which it was taken has also been examined. Metabolic experiments on an elaborate scale have been instituted with the view of investigating the problem, and no expense has been spared to obtain complete and accurate results, a large share of the costs having been borne by the Committee of Fifty for the Investigation of the Drink Problem. The results of the inquiry indicate that more than 98 per cent. of the ingested alcohol was oxidised in the body and that the potential energy of the alcohol was transformed into kinetic energy as completely as that of the ordinary nutrients. Alcohol appears to be very efficient in the protection of body fat from consumption, but not quite so efficient as the isodynamic amounts of the ordinary nutrients in the protection of body protein. The conclusion is drawn that so far as the utilisation of the total energy of the diet is concerned, there is a slight advantage in favour of the non-alcoholic diet, especially when the body is subjected to hard muscular exertion, but the difference is so small as to lie almost within the limits of experimental error.

The additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Semnopithecus cephalopterus*) from Ceylon, presented by Miss M. Wheatcroft; a Bonnet Monkey (*Macacus sinicus*, ♂) from India, presented by Mr. C. F. Taylor; a Green Monkey (*Cercopithecus callitrichus*) from West Africa; a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. R. M. Drury; an Australian Sheldrake (*Tadorna tadornoides*) from Australia, presented by Mr. W. Jamrach; an Egyptian Monitor (*Varanus niloticus*) from West Africa, presented by Mrs. Mary A. S. Deacon; two Cocteau's Skinks (*Macroscincus cocteaui*) from the Cape Verde Islands, presented by Mr. F. Newton; two Axolotls (*Amblystoma tigrinum*) from North America, presented by Mrs. Millicent Summers; a Spotted Salamander (*Salamander maculosa*), European, presented by Mr. R. R. Green; a Common Snake (*Tropidonotus natrix*), British, presented by Mr. E. Crane; a Grand Galago (*Galago crassicaudata*, var.) deposited; a Black-necked Swan (*Cygnus nigricollis*, ♀) from Antarctic America, purchased; a Rufous-necked Wallaby (*Macropus ruficollis*), a Common Wallaroo (*Macropus robustus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

CATALOGUE OF NEW DOUBLE STARS.—Mr. W. J. Hussey publishes, in No. 21 of the *Lick Observatory Bulletin*, the fifth catalogue of one hundred new double stars which he has discovered with the 12-inch and 36-inch refractors of the Lick Observatory, all these doubles having distances less than 5″.

Twenty-five per cent. of the five hundred pairs announced have distances not exceeding 0″·50, 48 per cent. not exceeding 1″·00, and 72 per cent. not exceeding 2″·00. The average distance for the five hundred pairs is 1″·52.

HYPOTHESIS ON THE NATURE OF SOLAR PROMINENCES.—Prof. W. H. Julius has described before the Royal Academy of Sciences (Amsterdam) a theory as to the nature of solar prominences.

It may be remembered that Prof. Julius accounted for the doubling of the arcs in the spectrograms obtained by him during the last total solar eclipse, by saying that it was due to the anomalous dispersion of the chromospheric light, and he now applies this theory of anomalous dispersion to account for solar prominences. He abandons the idea of the existence of various layers of different materials in the solar atmosphere, and suggests that "throughout the gaseous body, as well inside as outside the critical sphere, the various elements are altogether intrinsically mixed (granting that in the mixture the quantity of materials with greater specific gravity must grow with the depth)." It is suggested that, in the whirls formed by the ascent and descent of heated gases combined with the rotational velocity of the solar atmosphere, we get anomalous dispersion at the points where two or more of these whirls intersect and break each other; and the author goes on to propose "that the whole chromosphere with all its prominences is nothing but this system of waves and whirls, made visible within shorter or longer distances from the sun's edge by anomalous dispersion of light, coming from deeper layers."

Prof. Julius also points out that this theory abolishes the necessity for supposing the immense velocities which Fenyi and others have observed in connection with solar prominences, because it suggests that there is not a transmission of material, but only successive appearances of the same phenomena at various heights. He likens this to the apparent velocity of the line of foam caused by water waves breaking on a coast which is inclined to their wave-fronts (*Proceedings* of the Royal Academy of Sciences, Amsterdam).

VISIT OF THE ENGLISH ARBORICULTURAL SOCIETY TO COMPIÈGNE.

THE English Arboricultural Society held its annual meeting in London on Monday, August 18, and Mr. George Marshall, of Frimstone, Liphook, one of the members of the Royal Forestry Commission, was elected president for the year, in succession to Dr. Somerville, of the Board of Agriculture. M. Daubrée, Conseiller d'Etat and Directeur des Eaux et Forêts, was elected honorary vice-president, and four other French officers connected with the forests which were to be visited by the Society were elected honorary members.

On August 19, fifty-three members of the Society proceeded *viâ* Boulogne to Compiègne. Among these, besides our president, may be noted Mr. H. J. Elwes, F.R.S., of Colesborne, Gloucestershire; Mr. Coroner Graham, of Durham; Mr. F. W. Beadon, of Longley Hall, Huddersfield; Mr. J. Smith Hill, principal of the Agricultural College, Aspatria; Sir Hugh Beevor; Mr. J. Davidson, the secretary, in charge of the forests belonging to Greenwich Hospital; Mr. E. McA. Moir, late of the Indian Forest Department; Mr. Forrest, agent to the Duke of Bedford at Thorney; Mr. W. Forbes, forester to Lord Masham; Mr. Havelock, forester to Lord Yarborough; Mr. Gillanders, forester to the Duke of Northumberland; Mr. A. C. Forbes, forester to Lord Lansdowne, and many other foresters and nurserymen.

On August 20, the party proceeded to Villers Cotterêts (Aisne), the birthplace of Dumas, and spent the morning in inspecting the extensive timber yards of M. Carpentier and of the Chemin de Fer du Nord. The French band saws are the best in existence, and a very large quantity of fine beechwood is now being sawn up. The beech is sawn green during summer and then carefully seasoned, while oakwood is now being collected for autumn and winter sawing, hornbeam wood being sawn up in the spring. M. Carpentier sells much hornbeam wood in England. The system of creosoting by the Chemin de Fer du Nord is new. It is very effective, and was explained in detail and by practical illustration by the director. Large quantities of beech and oak sleepers are thus prepared, the beech absorbing three times as much creosote as the oak, and, as an experiment, a few maritime pine sleepers were being tried, this species not being yet used by this railway.

After breakfast, the party visited the Forêt de Retz (32,550 acres with a net revenue of 23,698*l.*), on undulating land 200 to 800 feet in altitude, the soil being chiefly a deep and fertile

loam above cerithic limestone, sand and quartzite. It is one of the finest forests in France, containing

Beech	40	per cent.
Hornbeam	40	,,
Pedunculate oak	15	,,
Sallow, poplar, chestnut and elm	3	,,
Conifers	2	,,

During the last thirty years, oak has been extensively planted in the young woods, so that it is hoped to raise the percentage of this species to 33 per cent. We inspected some of the regeneration areas and thinnings, under the guidance of M. Cottignies, Inspecteur des Eaux et Forêts, and his assistants, and were greatly pleased with the results, not a single blank existing in the forest.

On August 21, the Society visited the Forêt de Compiègne (36,072 acres with a gross revenue of 33,480*l.*). It is situated on a poorer and drier soil than that of the Forêt de Retz, half the area being flat and on Eocene sands and clay, the rest hilly (117 to 495 feet altitude) and above nummulitic sand and lime-

FIG. 1.—Sessile Oak in the Forêt de Bellême.
Girth at 4 ft. 6 in. = 9 ft. 9 in. Total height 119 ft. 6 in.

stone. M. Peiffer, Inspecteur des Eaux et Forêts, conducted us through the forest, which, when I saw it in 1871, was overstocked with red deer and rabbits, so that natural regeneration was rendered almost impossible. Although game is still important and produces an annual rental of 3880*l.*, yet it is now kept sufficiently in check, and the regeneration of the forest is proceeding satisfactorily, chiefly by natural seed. A practical illustration was given of setting free oak saplings from invasive growth of inferior species. This is done by the forest guards with a crescent-shaped cutting instrument having a handle about 4 feet long, and attracted much attention and commendation.

The party visited the splendid Château de Pierrefonds, which, under Napoleon III., was restored to its former condition in the middle ages by M. Violet le Duc, and from its watch-tower a most extensive forest panorama of the two forests of Retz and Compiègne was seen. We were then joined by M. Daubrée, the chief of the French Forest Department, and by the Conservateurs of Paris and Amiens, MM. Récopé and Molleveaux, and inspected the sessile oaks of the Beaux Monts. Such a mass of huge 300-year-old oak trees is to be seen only in France. A photograph of a French sessile oak taken by M. Granger, one of the Compiègne forest officers, is here reproduced.

The Mayor of Compiègne and the French officials dined with the Society in the covered courtyard of the hotel, which was ornamented with flags, creepers and evergreen trees. Besides the usual patriotic speeches by the president and the Mayor of Compiègne, Mr. Elwes, F.R.S., proposed the health of the French Forest Department in an excellent French speech, which was responded to most sympathetically by M. Daubrée, who invited the party to visit other French forests on some future occasion, and expressed his thanks for being elected one of our vice-presidents.

On August 22, most of the visitors went to Paris, some of whom visited the Forêt de Fontainebleau, but several proceeded to Valenciennes and spent two days in the splendid coppice-with-standards of the State forests of S. Amand (8290 acres) and the private forest of Raismes (3500 acres) belonging to the Duchesse d'Aremberg. These forests are on Tertiary sandy loam above the Coal-measures, and are noticeable for the equable distribution of standards (chiefly oak and ash) from ten to 120 years old. This is less marked in the State Forest,

FIG. 2.—Pedunculate Oak in the Forêt de S. Amand.

owing to wholesale felling of old oaks from 1790 to 1815. The ideal to be aimed at is to have 1400 cubic feet of standards per acre when the underwood is twenty-five years old, and to fell half this volume, leaving 700 cubic feet to grow for another twenty-five years, when it should again amount to 1400 cubic feet. A photograph is here given of one of these old standards, the distinctive growth of which, as compared with that of the oak grown in high forest, being noteworthy. During the Napoleonic wars, a large area in the forest of S. Amand had become mere heather and bracken waste; this was sown with Scotch pine about sixty years ago; the oak has sprung up naturally among these pines, which are being gradually removed every six years, and broad-leaved forest, chiefly of birch under oak standards, results. Each of these forests produces a net revenue of about £1 2*s.* 6*d.* per acre.

A full account of the notes taken in this expedition will be published in this year's *Proceedings* of the Society, the chief object gained being the continual discussion in the forest of interesting points of forestry by the members and the French foresters, and the demonstration of the successful following of a continuous plan through many decades for producing fine timber.

W. R. FISHER.

PALÆOLITHIC FRESCOES AND MURAL ENGRAVINGS.[1]

ATTENTION has already been drawn in NATURE (vol. lxv. p. 299) to the recent discovery of large mural decorations by Palæolithic artists, and as the subject is of such extraordinary interest we do not hesitate to give a further account of the more recent discoveries of like nature.

MM. Capitan and Breuil presented at the meeting of the Paris Academy of Sciences of June 23 a communication describing some paintings on the wall of the cavern of Font-de-Gaume in Dordogne. Of the eighty figures which are painted in red ochre and manganese black on the walls of the cave, forty nine are of bisons; all are engraved and painted, but sometimes the surface of the rock has also been scraped; a thick layer of stalagmite has covered many of the designs. The original of the figure of the running bison that we reproduce has a length of 1 m. ($39\frac{1}{2}$ in.) and a height of 60 cm. ($25\frac{1}{2}$ in.); it is entirely painted in a brown colour with a red tint on the forehead. These are the first frescoes recorded for France, as the engraved designs from the cave of La Mouthe, published by M. Émile Rivière in 1895, were rarely and, even so, but partially coloured.

M. Henri Moissan has analysed the colouring matters employed by the Palæolithic mural decorators, and finds that they are ochres composed of oxides of iron and manganese in variable proportions.

At the meeting of the Academy on July 28, M. Émile Rivière drew a distinction between the true frescoes described by the former authors and his own discoveries in the cave of La

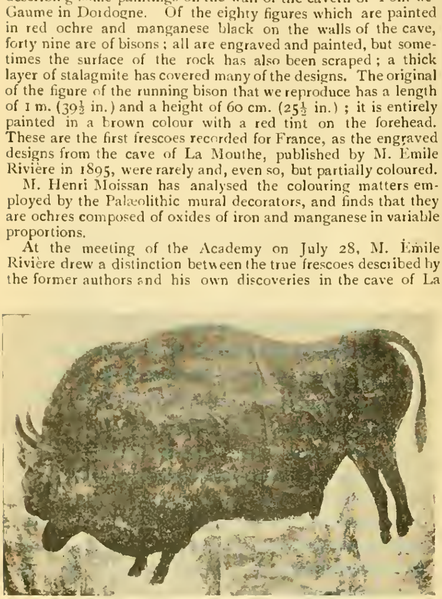

FIG. 1.—Fresco of a Bison, Font-de-Gaume.

Mouthe, also in Dordogne. The latter are almost exclusively more or less deep engravings or shallow markings produced by scraping or scratching the rock. Two of the figures present some traces of paint; one of these represents a ruminant, perhaps *Bos priscus*; the contour only of the hind limb is coloured a blackish red-brown, especially at the level of the joints and hoofs; the left flank of the animal is marked with ten spots of the same blackish-brown colour, extending in a line from the shoulder to the upper portion of the thigh. The other design represents a kind of hut, not engraved by a simple line which indicates the contour as in the numerous animals represented upon the walls of La Mouthe, but by a scraping of the rock. Ochre (possibly mixed with manganese) has been applied superficially to portions of the scratches in such a manner that the colour is much less deep than in the former figure; it is laid on in a series of bands approximately parallel and alternately clear and dark. This is the only known drawing of a habitation of primitive man.

M. Rivière does not commit himself as to the contemporaneity, or otherwise, of the engravings of La Mouthe with the paintings of the Font-de-Gaume; but he reasserts that the figures of La Mouthe are undeniably Palæolithic (Magdalenian), and, geologically speaking, of the Quaternary epoch. The prehistoric artist who engraved them was the contemporary of the reindeer and of the mammoth the portraits of which he delineated.

In a recent number of *l'Anthropologie* (t. xiii. Mai–Juin, 1902), M. Emile Cartailhac gracefully acknowledges that he was wrong in doubting the genuineness of the pictographs of animals painted on the walls of the cave of Altamira in Spain. He gives two illustrations of these frescoes, one of which (Fig. 1, p. 351) contains a group of seventeen animals, drawn with spirit and with a considerable degree of accuracy. The Altamira artist, or artists, evidently belonged to the same "school" and period as that of the Font-de-Gaume artists.

SEA TEMPERATURE VARIATIONS ON THE BRITISH COASTS.

THE Meteorological Office pilot chart for September contains very interesting information relating to the temperature of the sea water round the coasts of the United Kingdom in the month of June last. Over nearly the whole of the Atlantic between the 30th and 50th parallels the temperature for the month was below the average, in many places the deficiency amounting to 5° and upwards. This fact is clearly shown on the general chart, but two small charts have been added to illustrate a remarkable change experienced close inshore. Daily records at a large number of coastguard stations and lightships disclose the prevalence of very cold water during a considerable part of the month, and a rapid increase of warmth towards the close. The extra sketches exhibit the mean results for June 1 to 24 and June 25 to 30 respectively. Along the western and southern coasts, many of the minimum values during the cold

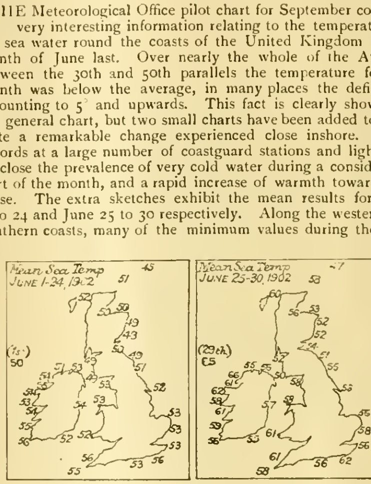

FIG. 1.—Sea Temperature Variations on the British Coasts.

period were as low as 48° to 52°, the lowest in several places occurring as late as the 15th of the month. Off Eastbourne, 54° on the 8th and 9th was the lowest June record in nineteen years. On the east of Britain and west of Scotland the minima were from 42° to 48°. Before the end of the month the west and south coasts were generally above 60°, and the east and north 55° to 60° and upwards. Up the north-western shores the temperatures were higher than in any other neighbourhood, the maxima being registered on the 28th or 29th as a rule. Stornoway and Seafield touched 66°, Ballyglass 67°, Liscannor 68°, Teelin Head 70°, and Blacksod Point 72°. Even the Orkneys reached 60°, while Eastbourne did not pass 62°. Confirmation of these very high readings in the north-west is afforded by the records of ships well out in the offing, the observations in about $55\frac{1}{2}$° N., $11\frac{1}{2}$° W., showing 50° on the 1st and 65° on the 29th.

Judging by the mean results for the two periods, the greatest change took place off Teelin Head, Donegal, where the closing days averaged 12° warmer than the previous part of the month. Blacksod, to the south, was 8°, Arran Island 7°, Seafield 5° and Minard 4° warmer, while Ballydonegan, at the south-west extremity of Ireland, showed no change. Northward from Teelin Head we find a rise of 8° at Stornoway, 7° at the Orkneys, and, curving southward down the coast of Caithness, 6 at Cromarty. The warmth scarcely affected the Shetlands, where the increase was only 2°. Eastward past the north of Ireland the effect diminished rapidly, the rise at Sheephaven being 4°, at Port Rush and Lamlash 3°, and at Ballantrae 1°. For the warm period the Orkneys equalled and the Hebrides exceeded by 2° the result at Scilly, 58°. It must be remembered

in connection with this phenomenon that the country experienced almost the only few days of warm weather of the summer, but while the water was decidedly warmer in the north-west than elsewhere, the air temperature was higher over England than over the south of Ireland, and still higher than in the north of Ireland.

RECENT EDUCATIONAL REPORTS.[1]

THE protracted discussions in the House of Commons, the numerous leading articles in the newspapers and the frequent public speeches of politicians, concerned with the subject of education, with which we have been provided during the past six months, are evidence enough that English people are at least beginning to be interested in the important question of the provision made by the State for the education of its citizens. But interest alone is not enough, it must be intelligent; and to ensure this it is important that the instructors of public opinion should themselves be well informed, both as to what is actually happening in the schools and colleges of our own country and as to the systems of education in other lands. For these and similar reasons, the special reports published from time to time by the Board of Education, under the editorship of Mr. Michael E. Sadler, the director of special inquiries, have a peculiar value just now; while the general reports of H.M. Inspectors serve admirably to remind Members of Parliament that despite the changes which may be necessary in our educational administration, good, thorough work is even now being accomplished in most of our State-aided schools, whether elementary or secondary.

The two volumes dealing with education in the United States of America are concerned more with general principles and tendencies than with specific details as to methods of instruction. Though this will detract from their value to practical teachers, it gives greater opportunities to insist upon the necessity for the possession by our legislators of proper, high ideals as to the function of education. As Mr. Sadler says in a paper he contributes to the second volume, "a national system of education which made money-getting its central aim would deserve all the contumely which history in a more enlightened future would be certain to heap upon it." American educators are showing the world that it is possible at the same time to develop the higher faculties, to have a due regard to the pleasures of cultivated leisure, to encourage "sweetness and light," and yet thoroughly to equip their young men with a knowledge of recent advances in pure and applied science, so that without difficulty they may take an honourable part in the production of those material comforts without which the most cultured would find it hard to live.

Two factors, among many others, preeminently contribute to the success of American education. In the first place, there is the munificence of wealthy Americans. Mr. Percy Ashley, at the end of his article on American universities, tabulates the total amount of benefactions reported during the years 1890–1901. During these eleven years, very nearly twenty-three millions of pounds were given to higher educational institutions, not including libraries and museums, and more than two millions went to the Leland Stanford University alone. These princely sums are largely devoted to the encouragement of research; as Mr. Ashley says:—"In all the arrangements for research work the United States is much under German influence; and it is greatly to be regretted that England should be so far behind . . . In spite of the establishment in recent years of degrees avowedly for research by Oxford and Cambridge, there is still no place where organised research work is carried on in England . . . It must be said that the research work of the American universities is probably the part of their activity most worthy of study by those interested in academic progress in England. It must be admitted, however, that the material attractions to research and an academic career are far stronger in the United States than here."

[1] "Special Reports on Educational Subjects." Vol. x. "Education in the United States of America." Part i. Pp. 538. Price 2*s*. 3*d*. Vol. xi. "Education in the United States of America." Part ii. Pp. 624. Price 2*s*. 6*d*. (Eyre and Spottiswoode.)
"General Reports of H.M. Inspectors on Elementary Schools and Training Colleges for the year 1901." Pp. 234. (Eyre and Spottiswoode.) Price 1*s*.
"General Reports of H.M. Inspectors on Science and Art Schools and Classes and Evening Schools." Pp. 98. (Eyre and Spottiswoode.) Price 5½*d*.

The second factor in the success of American education to which reference has been made is the recognition of the existence of a science, as well as an art, of education. Sir Joshua Fitch points out in his introductory paper that "America may be regarded as a laboratory in which educational experiments are being tried on a great scale, under conditions exceptionally favourable to the encouragement of inventiveness and fresh enthusiasm, and to the discovery of new methods and new truths." The experimenters are, moreover, well trained for their work. There is little scepticism as to the value of training for teachers in the minds of American authorities, and some idea of the pains taken to make the training as helpful and practical as possible can be obtained from Dr. Russell's account of the admirable Teacher's College of Columbia University, included in Part i. of the report. Among the numerous proofs, contained in these pages, of the success attained by the teachers proceeding from American training colleges, President Hadley's opinion may be quoted:—"Our best American schools of technology are no longer places for shop work, but places for the training of thinkers—of men who may not know how to do the particular things which will first be wanted of them, but who are in possession of that general knowledge which will enable them to learn more thoroughly the real bearings of any new problem as it arises. They have become less technical and more scientific."

The space available allows only the briefest reference to the general reports of H.M. Inspectors. Attention must, however, be called to the remarks of Mr. Pullinger, Chief Inspector of science and art schools in the northern division of England, on the work of evening continuation schools. He finds that many of the pupils in these schools "come for warmth, for the comforts of an attractive, well-lighted room, for the monthly lantern lectures and for the free trip to Blackpool at the end of the session." The schools have been variously described as "gather-'em-in-at-any-price-schools" and as "a sort of shelter for homeless boys and girls." Mr. Pullinger wishes "to state emphatically that the supply of really educational night schools is most inadequate." When it is remembered that the evening classes of our technical schools have largely to rely upon the preliminary training given to their students at these evening continuation schools, the immediate necessity for their improvement becomes evident, and it is to be hoped that the Board of Education will refuse its grants to all schools where the chief aim is recreative.

SNOW-WAVES AND SNOW-DRIFTS.[1]

THE primary object of a visit to Canada at the end of 1900 was to continue the investigation of terrestrial surface waves and wave-like surfaces, without, however, confining attention entirely to the study of such forms or motions of the snow as might be wave-like in character.

In Canada a geographical distribution of the kinds of snow was noticed. Near Montreal the snow was, on the whole, only moderately dry, and during December did not differ very much from what was seen in Scotland, on the Pentland Hills and near Grantown-on-Spey, during February, 1900, except that the freshly fallen flakes did not cling together to form mottling and rippling. The forms of the snow-drifts, or banks, in the neighbourhood of obstacles were not very dissimilar. The same general character of snow was observed as far west as Port Arthur, 1000 miles by rail from Montreal, the surface of the snow being generally soft. Near Winnipeg and westwards, at least as far as Medicine Hat, the appearance of the snow-banks accumulated in the neighbourhood of obstacles was strikingly different. Here the snow was almost perfectly dry and the snowfall light. The prairie was often swept quite bare of snow in the neighbourhood of the banks, and the surface of the snow on the prairie was generally hard and rough. But for its whiteness, the landscape resembled a desert with low isolated sand-hills more than a snow-scene in England. Much of this snow was granular, like sand, as the result of processes which it had undergone since its deposition.

On reaching the Rockies, the snow was seen to resemble more that of eastern Canada, but afterwards it became, apparently, still more moist, so that, in the next range, the

[1] Abridged from a paper by Dr. Vaughan Cornish, read before the Geographical Society on May 12 and published in the August number of the *Geographical Journal*.

Selkirks, perfect examples of the forms which gravity imparts to moist snow were met with.

FIG. 1.—A Snow-mushroom nine feet in diameter.

At Glacier House a tree stump 2 feet in diameter had a cap of snow 9 feet across, the eaves projecting 3 feet 6 inches all round the pedestal. A broken tree with diameter of 4 feet had a snow-cap 12 feet across, the eaves projecting 4 feet beyond the pedestal (Fig. 1). Some of these snow-mushrooms must have weighed a ton.

That the "snow-mushroom" is, on the whole, so remarkably preserved from ruin by overloading may be attributed to bending of the strata under the action of gravity, their inclination to the horizon increasing with the distance from the pedestal.

Waves of drifting snow are only formed in dry snow at a low temperature. They are not so steep as the corresponding sand-waves.

Even when the surface is all covered with fresh snow, an extensive horizontal plain appears to be the best field for the growth of snow-waves, for the liability to local *surcharge* increases with the extent of the field of drifting. The more unlevel is the country, and the more numerous the places of shelter, the shorter is the time during which the wind can drift the snow in waves, and the smaller is the extension of the individual groups of waves.

Snow-fences are commonly erected in Canada to check the rate of snow-drifting. After the first snowfall, a snow bank or drift is produced, having a moderately gentle slope to windward and a cliff or cornice on the lee side. The form resembles that of a sand-dune or any other wave of a drifted powder, which at first suggests that the form proper to a drift caused by the fence is similar to that of freely drifting snow. This, however, is not the case, for the structure is as yet incomplete, owing to insufficient supply of the material. Succeeding snowfalls build out the drift with a diminishing cliff, until we have at last, perhaps not until nearly the end of winter, the completed form in which there is no lee cliff, but a long, gently tapering slope on the lee side, the weather face retaining its original form and *relatively* steep slope.

When we have to do with large bluffs or cliffs, the whole of the winter's snow is not sufficient to fill in the area of eddies on the sheltered side so as to reduce the surface to "easy lines." Thus the largest drifts are never of completed form, but have always a steep face to leeward. Completed drifts, having no shadow-throwing cliffs, are also much less conspicuous relatively to their size. Thus circumstances combine to prevent the casual observer from discovering what is the profile really proper to a snow-drift.

From an examination of the snow-drifts in Canada, the conclusion was reached that a curve of the character shown in Fig. 2, with the blunt end towards the wind, was the fundamental element of their form.

FIG. 2.—The fundamental Curve of Snow-drifts.

This, which may be termed the *ichthyoid curve*, is the profile of *completed* drifts in the neighbourhood of obstructions on the prairie.

Inverted, it is the profile of the holes round trees, as observed in the woods near Montreal.

Viewed in plan, it is the curve cut out in the snow round the end of a wall.

Viewed in plan together with its image, it is a boundary curve enclosing the horseshoe-shaped banks round houses near Winnipeg, and equally the hollows round trees or stones.

This doubled curve has the generalised form of a fish,[1] or if it be spun round so as to give the outline of a solid body, we have the modern Whitehead torpedo with the blunter head now preferred to the older sharp-nosed form.

The analogy to the fish-form is still more striking if fishes are looked at from above instead of viewing them in profile.

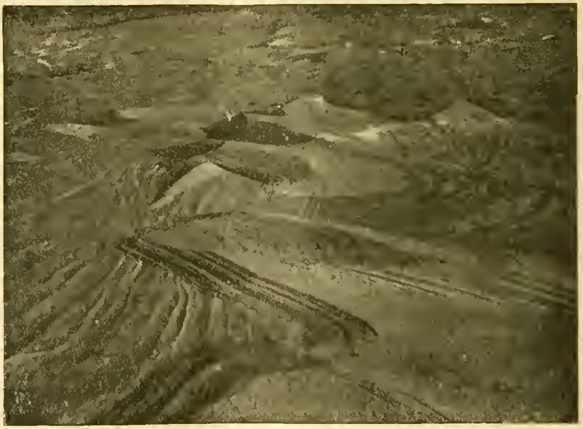

FIG. 3.—Stratification of Snow revealed by Wind Erosion.

The completed snow-drift in the neighbourhood of an obstruc-

[1] The profile of the snow-drift resembles the profile of a sole or other flat fish.

tion may be regarded as a filling in of the eddy-space in such a way as to provide easy lines for the flow of the wind.

In waves into which freely drifting powders fall, the steep side is on the leeward instead of upon the windward, and this signifies that the eddy-space is *never* filled up. The whole eddy-space is, in fact, free to move forward, and does so when the snow is drifting, and this progression is the wave motion.

The relation between the profile of the snow-drift and that of the waves of drifting snow and sand may be further illustrated by drawing the profile of the wave, not in the usual way, from trough to trough, but from crest to crest. It is then seen that the unfilled space between the two ridges has the blunt nose and fine tail profile; that it is the profile of the hollows in snow round trees and of the fuljes of sandy deserts, the form proper to an eddy space.

The powder, when drifting in waves, has the "fine nose and blunt tail form," which is that of greater eddy-making resistance (the nose being that part turned towards the wind), and the powder, when in its complete accumulation near fixed obstructions, assumes the "blunt nose and fine tail" form, which is that of less eddy-making resistance. Both forms are simultaneously produced on a snow-field, and both are compatible with the removal by the wind of the maximum quantity of snow in the course of the winter. Thus, on the one hand, the maintenance of strong eddies in the drifting waves evidently increases the power of the wind to drive the snow before it; and the hindrance offered by a fixed obstruction is best minimised by filling in its eddy-space with a structure which shall thereafter absorb as little energy from the wind as possible.

Sometimes the freely drifting snow is accumulated in isolated hillocks, which have been called barchans or medaños. Sometimes their development from patches of drift snow can be observed. These patches have in ground plan a fine nose towards the wind and a blunt tail or lee end—a sort of delta shape, but with curved sides. The same thing may be seen in sand. This is in accordance with the habit of the freely drifting snow to adopt a fine nose and blunt tail arrangement in vertical profile.

Freely moving barchans of less or greater elongation probably fill in less or more of the narrow end of the ichthyoid curve. The crest of the cliff will be lower than the summit of the barchan if the former be beyond the broadest part of the curve. The erosion forms produced by wind when acting upon consolidated snow were also studied. Fig. 3 shows how the minute stratification of the snow is revealed by the action of the wind.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE following list of candidates successful in this year's competition for the Whitworth scholarships and exhibitions has been issued by the Board of Education, South Kensington:—Scholarships, 125*l*. a year each (tenable for three years):—William M. Selvey, London; Leonard Bairstow, Halifax; Isaac V. Robinson, West Hartlepool; Arthur Baker, Gosport, Hants. Exhibitions, 50*l*. (tenable for one year):—Charles Cook, Landport, Portsmouth; John S. Mitchell, Uddingston, near Glasgow; Charles J. Stewart, Fratton, Portsmouth; Arnold H. Gibson, Sowerby Bridge, Manchester; William E. W. Millington, Hollinwood, Oldham; Neil J. Maclean, Kelvinside, Glasgow; Henry J. Jones, Southsea; Harold Rawstron, Oldham; George H. Childs, Portsmouth; Norman L. Ablett, London; William E. F. Curror, Ilford, Essex; Walter L. Port, Brighton; John Alexander, Glasgow; Louis D. Stansfeld, London; Robert J. A. Pearson, Sheffield; William L. Perry, Plymouth; Arthur S. Angwin, London; Francis G. Steed, Devonport; Henry A. Bagg, London; Frederick J. Crabbe, Southsea; Arthur Garrard, Forest Gate, E.; Benjamin J. Thomas, Devonport; Maurice B. Dalby, Gateshead; Thomas Wadhams, Wolverton; Oliver S. Spokes, Crewe; James Crone, Charlton, Kent; Alexander B. Sowter, Glasgow; Fred Sykes, Huddersfield; Frederick E. Rebbeck, Belfast; Frank W. Harris, Swindon.

THE metropolitan and most of the provincial medical schools will be opened at the beginning of October. Among the addresses to be delivered, the following are announced:—*Charing Cross Hospital*. The fourth biennial Huxley lecture on "Recent Advances in Science and their Bearing on Medicine and Surgery," by Prof. W. H. Welch, of the Johns Hopkins University, Baltimore. *St. George's Hospital*. Address by Dr. T. T. Whipham. *St. Mary's Hospital*. An address by Sir A. W. Rücker, F.R.S. *Middlesex Hospital*. Mr. Stephen Paget will give an address. *University College*. An address by Mr. Percy Flemming. *London (Royal Free Hospital) School of Medicine for Women*. Address by Mr. Charles Burt. *School of Pharmacy*. Address by Dr. W. Palmer Wynne, F.R.S. *Royal Veterinary College*. Address by Prof. Bottomley. *Yorkshire College, Leeds*. Address by Mr. A. W. Mayo Robson. *University College, Sheffield*. Address by Sir H. G. Howse. *Owens College, Manchester*. Address by Sir Dyce Duckworth. *University College of South Wales and Monmouthshire, Cardiff*. Address by Dr. Berry Hart.

A SUMMARY of the more important recommendations contained in the report of the Indian Universities Commission, which has now been published in India, is given in the *Pioneer Mail* of August 8. Among other points, it is recommended that in addition to holding examinations, all universities should be recognised as teaching universities, and that there should be no more than five faculties, viz. arts, science, law, medicine and engineering. One regulation is certainly a tribute to the power of memorising possessed by the oriental mind; it is prescribed that "text-books to be read should be so long as to exclude the possibility of all of them being committed to memory"; another lays it down that "students should not be required to pass in science before entering on the University course. Instruction should include practical experimental work, and in examinations for the B.Sc., the practical examinations should be passed independently of the written examinations, and should have a separate minimum of marks. . . . The degree of D.Sc. should require original research." The improvement of the equipment of medical colleges is urged, as well as the establishment of a diploma of sanitary science. The universities are not recommended to undertake instruction in engineering, but are advised to encourage agricultural and commercial studies. We agree with the concluding remark of the commissioners, that "it is better for India that a comparatively small number of young men should receive a sound and liberal education than that a large number should be passed through an inadequate course of instruction leading to a depreciated degree."

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, (2) vol. viii. No. 10 (July).—E. J. Wilczynski, account of the first meeting of the San Francisco section, with abstracts of the papers read.—Mary M. Newson, a translation of Hilbert's lecture on mathematical problems (delivered at the Paris Congress, 1900).

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 24.—"On Skin Currents. Part iii. The Human Skin." By Augustus D. Waller, M.D., F.R.S. (from the Physiological Laboratory of the University of London).

In freshly removed healthy skin, the normal current is always ingoing and the response to electrical excitation by the induction coil is always outgoing. This response, called by Dr. Waller the "blaze," is a sign of its vitality, is independent of the normal current and amounts to from 0·0100 to 0·0400 volt, if tested, within forty-eight hours after removal, by tetanising currents of alternating direction in both pairs of direction.

Moribund skin and skin from post-mortem room give small reactions of variable direction amounting to not more than ten-thousandths of a volt.

In all cases, the electrodes were carefully tested and the skin subsequently killed by boiling, tested and found to give negative results.

The following observation is illustrative. A piece of skin of breast one-and-a-half hours after removal gave 0·0180 and 0·0230 volt in response to single shocks of both directions. On the third day the reactions were 0·0050 and 0·0175, on the fourth day 0·0025 and 0·0035. In all cases, this was abolished by boiling.

A remarkable feature was the great diminution of resistance of living skin caused by tetanisation. The resistance of dead skin is far below that of living skin and is unaltered by tetanisation. Fatigue is exhibited more in human skin than in frog's kin.

As regards the locality of the reaction, Dr. Waller finds that the blaze currents arise exclusively from the malpighian layer of the epithelium, not from the superficial keratinised cells, or from the subcutaneous tissue and the corium; he demonstrates this by means of a three-way key leading off from three electrodes, of which one, A, is on the external surface, B on the internal opposed surface, C on an external indifferent part. Excitation is made through A B and the result is led off from A C and from B C; there is response from A C, but not from B C, showing that the under surface B gives no reaction. The blaze reaction is quite local and is not propagated to any distance from the excited spot, and adjacent portions exhibit different degrees of vitality.

The apparent duration of vitality is surprising, lasting as long as ten days after excision.

The remarkable augmentation of conductivity by tetanisation may be due to, first, a "Kataphoric" migration of water, second, to a dissociation of electrolytes. Dr. Waller is inclined towards the second alternative.

Alterations of temperature produce alterations of resistance as in any moist conductor. In the case of living skin, Dr. Waller has witnessed at the moment of congelation (-4° to -6° of the cooling chamber) a sudden electromotive discharge of 0·0080 volt attributable to the sudden excitation of living matter in the act of congelation. On return of the frozen skin to the original temperature, the resistance was found to be much reduced and the response to excitation was abolished.

PARIS.

Academy of Sciences, August 23.—M. Bouquet de la Grye in the chair.—Short period solar and meteorological variations, by Sir Norman Lockyer, K.C.B., and Dr. William Lockyer. A comparison of the curves, for a period of from fifteen to thirty years, of sun-spots, prominences, atmospheric pressure and rainfall in India. By comparing the solar data with the terrestrial atmospheric pressure, the conclusion is reached that the eruptions of prominences, coinciding with the variations of latitude shown by the spots about every three and a half years, are the true causes of a variation of air pressure on the earth.—The relation between the solar protuberances and terrestrial magnetism, by Sir Norman Lockyer, K.C.B. An examination of Italian observations made during the last thirty years has shown that the epochs of the solar storms classed as great by Ellis are identical with those of the greatest chromospheric activity near the poles of the sun, whilst the general curve of terrestrial magnetic activity is very nearly the same as that of the prominences observed near the solar equator.—The theoretical study of resistance to compression of mortar, by M. Considère.—On the methods of concentrating liquids used for food, and especially wine, by M. F. Garrigou. By distilling wine in a vacuum, it has been found possible to reduce the wine to one-fourth of its original bulk, without losing any of its aroma or alcohol.—Mechanical treatment in the milk industry, by MM. F. Bordas and Sig. de Raczkowski. The number of bacteria in a cubic centimetre of milk capable of forming colonies under plate cultivation was determined in the milk as it left the udder, in the mass of milk 24 and 36 hours after milking, in the one case where it had not been touched by hand, and in the other after the usual amount of handling. In some cases, special antiseptic precautions were taken. The results show that there is no difficulty in keeping the various pipes and taps used in connection with the mechanical treatment sterile, and at the same time there is greater safeguard against accidental contamination.—The structure of the suprarenal bodies of the Plagiostoma, by M. E. Grynfeltt.

NEW SOUTH WALES.

Royal Society, July 2.—Prof. Warren, president, in the chair.—Notes on two chemical constituents from the Eucalypts, by Mr. Henry G. Smith.—In this paper, the author records the results of continued investigations on the ester (geranyl-acetate) contained in the oil of *Eucalyptus Macarthuri*, and also on the oil itself. These data show that the ester does not fall, at any time of the year, below 60 per cent., and that the amount of free alcohol, considered as geraniol, diminishes in amount as the ester increases. The greatest amount of naturally formed ester occurring at any time of the year was 74·9 per cent. in September, but the free alcohol was only 6 per cent., at that time. It has been found from numerous determinations that when the oil is acetylised the ester content will be but little removed from 80 per cent. The oil does not contain phellandrene at any time of the year, and eucalyptol appears to be always absent. Eudesmol is always present, but as it varies in amount the specific gravity of the oil varies also. The crude oil appears to be always slightly dextrorotatory. From the results of investigation of the oil obtained from more than 100 distinct species of Eucalypts, this is the only one found to contain this valuable oil.—The aboriginal languages of Victoria, by Mr. R. H. Mathews.—The parks of Sydney; some of the problems of control and management, by Mr. J. H. Maiden.

TRIANGULATION OF SOUTH AFRICA.

Geodetic Survey of South Africa. Vol. ii. *Report on a Rediscussion of Bailey's and Fourcade's Surveys and their Reduction to the System of the Geodetic Survey.* By Sir David Gill, K.C.B., LL.D., F.R.S, &c., H.M. Astronomer at the Cape. Pp. xx + 257. (Cape Town, 1901.)

THE Geodetic Survey of Cape Colony and Natal was carried out in the years 1883-92 by Colonel Morris, C.B., C.M.G., R.E., under the direction of Sir David Gill, and the results were published in the report issued in 1896.

The present volume is entitled vol. ii. of the Geodetic Survey, although, as Sir David Gill points out, its contents are not strictly of a geodetic character. As, however, many of the points are connected with stations of the Geodetic Survey, "with all the accuracy required for astronomical geodetic stations, it has been considered convenient to preserve the results in the same series of publications."

This vol. ii., then, is a discussion of the secondary triangulation carried out by Captain Bailey, R.E., in the years 1859-62, and of that executed by Mr. Fourcade, of the Forestry Department (in 1893?). These triangulations extend along the southern coast of South Africa from Cape Town to East London, a distance of about 550 miles, and have an average width of about 75 miles, covering an area of some 40,000 square miles. The probable error of an observed angle of Bailey's triangulation is about $\pm 2''\cdot 0$; of Fourcade's, $\pm 0''\cdot 85$. The number of points fixed is 133.

The history of the computation of Bailey's work is somewhat curious. In 1862 the Survey party embarked at Algoa Bay for England in a coasting steamer. The vessel struck upon the rocks off Struy's Point and became a total wreck. The original observation books were all lost. Fortunately, copies of abstracts of angles had been supplied to the Admiralty Surveyor, then at work on the Coast Survey, and other abstracts with a diagram had been sent to the Surveyor-General, to the Government of British Kaffraria, and to private individuals and surveyors, and from these a report was compiled by Captain Bailey and presented to the Cape Parliament in 1863. On the completion of the Geodetic Survey, however, it became obviously necessary to harmonise Bailey's work with the geodetic triangulation.

Throughout the length of the secondary work there are many sides which are common to it and the geodetic triangulation. The secondary triangulation has therefore been broken up into a number of small manageable figures. In these figures the number of equations of condition averages about ten, and in the reduction the geodetic triangulation is considered errorless, and its sides and angles enter as fixed quantities.

The net result is an important addition to the triangulation of South Africa. The volume is all the more valuable for the fact that the results of the Geodetic Survey (the report of which is now out of print) have been reprinted in the present report, which contains the whole of the accurate trigonometrical data in the Cape Colony and Natal which had been completed up to the year 1901. It may be hoped that the day is not far distant when this work will be used as the basis of the much-needed, long-delayed topographical survey.

Sir David Gill ends his preface with a remark which several national surveys might take to heart with advantage :—

"It is also of supreme importance that regular inspection of the Survey beacons should be instituted, and steps taken to provide for their repair and maintenance . . . it is most necessary in the public interest that these invaluable land-marks, which have cost so much in labour, skill and care to establish, should in future be more carefully preserved."

It may be noted that this is a duty which in India has long been recognised and carried out by the Government. C. F. CLOSE.

VITALITY.

Religio Medici, &c. By a Student of Science and Medicine. Pp. viii + 216. (London: Good and Co., 1902.)

THE reader of this book is at first sight beset by two prejudices; the title, as printed on the back of it, "Religio Medici," is one which a great writer has made his own, a writer whose weight and intensity stand in contrast with the diffuseness and repetition of the present author; and secondly, the type is so small and defective that the labour of perusal is out of all proportion, so the reviewer is apt to think, to the value of the contents. A distant imitation of Sir Thomas Browne's conciseness would have halved these contents, at least; and thus reduced the cost of production by means better than inferior print. At the hundredth page our eyes gave out; but, after a glance at the remainder, we think in the first moiety one may read the whole.

The main purpose of the author is, by an argument which is similar to that of Dr. Lionel Beale, if not identical with it, to assert that "vitality" or "life power" belongs to the spiritual as opposed to the physical or material category, the realm of life being separate from the realm of matter. The end or purpose of this argument is not, of course, to be flouted because it cuts at the root of modern conceptions from which such entities have been dismissed; nay, even if the author regards force as something acting upon matter, as a bellows upon sand, it does not become us to throw his book aside because we have outgrown or parted company with such opinions. Evidently the author is not only an earnest and high-minded thinker, but also an accomplished scientific observer. His skill in the use of the microscope and its methods is probably considerable. But, while our minds are open and our respect for the writer is great, before we occupy our space with so vast a discussion we must have reasonable expectation of getting close to the points of issue. Of this approximation we see little hope. In the first place, it is inconceivable that modern conceptions will ever be put on the shelf that older opinions may be taken up again in their former

shape. Modern conceptions will, we trust, give way to others larger and better; in this author and reviewer are at one: yet their supersession will be by no such repentance, but by a wider and richer synthesis in which, no doubt, earlier and later opinions will find their reconciliation. To throw new ideas aside just to pick up certain old ones which, in substantially the same form, have prevailed and then lost their ascendancy, is what in the history of ideas has never happened, and, it is safe to say, never will happen. Secondly, to remodel our conceptions of life the thinker must not only be equipped, as no doubt the author is equipped, with skill in certain processes of research, but he must be equipped also with a philosophic grasp and penetration of which we see little evidence here. Besides the diffuse, reiterating and even rambling way of dealing with the subject on which we have animadverted, the author has neither rigidly defined his terms (such as "physical," "mechanical," &c.) nor repeated them even in approximately identical senses. Slovenly argument and confusion of language can only lead into the desert.

The author deprecates rash speculation; no speculation can be more ambitious than his, and it is none the less so for being elderly and familiar. The doctrines of the survival of the fittest may be "ingenious and fanciful," but his own are no less audacious and stand on supports at least as fragile.

In conclusion, we must content ourselves with pointing out that vital phenomena depend upon causes either of like nature to those which are in action in heat, light, chemical affinity and so forth, or they depend upon some intrusive entity of alien origin. The author holds the latter opinion. We must invite those who hold this opinion to explain whether in their hypothesis those which we will call the natural forces are superseded by the transcendental or not? So far as our knowledge goes, they are converted, but neither superseded nor curtailed; yet in this case how are we to conceive of them as entering into any sort of combination with agents with which they have no affinity whatsoever?

OUR BOOK SHELF.

Elements of Physics. By C. Henderson, Ph.D., and John F. Woodhull, Ph.D. Pp. x + 388; with illustrations and portraits.

Physical Experiments. By John F. Woodhull, Ph.D., and M. B. van Arsdale. Pp. iv + 112. (London: Hirschfeld Bros., Ltd., 1902). Price 5*s.* net bound together.

IT is to be feared that the former of these books (which are bound together) must be condemned if only for the astounding way in which optical images are considered. The image in a concave mirror is taken as being at the same distance behind the mirror as the object is in front, "because this seemed to be as reasonable as any other conclusion and it is a convenient measurement." This rule makes the image curved, and thus its distortion is explained. Even the usual inverted image is placed and its magnitude determined in accordance with the above rule. Extraordinary statements such as these in the chapter on light make it impossible to recommend that the book be placed in the hands of school children, for whom it is intended. The other portions are not affected with such general misconceptions, although they are not wholly free from serious error. Thus on p. 262 it is stated that a 32 c.p. lamp requires twice the current of a 16 c.p. lamp, and that this may be obtained either by doubling the voltage or halving the resistance. "In any case the heat and light will be proportional to the amount of current which passes." On p. 205, in connection with latent heat, "Farmers understand this and put tubs of water in their vegetable cellars on a cold night so that if the temperature falls below 32° F. the freezing of the water will give out such quantities of heat as shall prevent the temperature from falling far below 32°."

These mistakes are to be regretted the more because the authors appear to have striven to give, and in many cases have succeeded in giving, a lucid introductory account of the many phenomena dealt with.

The experimental book contains a very good selection of experiments for school use. The discription given is too brief except as a general guide to the teacher.

A. W. P.

Types of British Plants. By C. S. Colman. Pp. xii + 238. (London: Sands and Co., 1902.) Price 6*s.*

THIS is a volume which is intended to attract and teach the young naturalist. It presents a short general introduction, systematic and anatomical; it then traces out a developmental course, which begins with the simple unicellular algæ, works up through the more complex cryptogams and finally passes in review the principal phanerogamic orders. In addition, a few chapters are given up to special features, notably trees, parasites and insectivorous plants. Apart from the fact that no worse system could be adopted than that of placing before a beginner a number of facts loosely strung together, this book has the further disadvantage of starting with the lower plants, which are more difficult of comprehension and less suited to practical examination. The descriptions, too, of the lower plants, besides being so scrappy as to be valueless, are couched in ridiculous language. Why talk of "father pits" and "mother pits" in Fucus, or of a "nursery" in Vaucheria, or of "cheerful conviction" as applied to Phallus. A facetious mode of expression, which implies that plants possess the attribute of consciousness, runs through the book. Unfortunately, too many writers think that loose or facetious phraseology is necessary to make a book popular; it certainly detracts from the value of any scientific work.

Water-Supply. By Prof. William P. Mason. Third Edition, Rewritten. Pp. vii + 448. (New York; John Wiley and Sons; London: Chapman and Hall, Ltd., 1902.)

THIS is the third edition of a work which has met with much appreciation both in this country and in America, for the writer is a recognised authority upon the subject with which he deals. Those who were familiar with the first two editions will note that in the present volume a considerable amount of new material has been added, and that the original chapters on "The Chemical and Bacteriological Examination of Water" have not been included—for the reason that they have been separately published.

There is nothing connected with water-supply—save engineering details of construction of water-works, &c.—on which this volume may not be consulted with value. The writer has an intimate knowledge of his subject, which has been gained by a wide experience. His information and experience is not limited to America, and the work is additionally acceptable to British readers from this circumstance—which is a somewhat exceptionable one among American writers of works dealing with sanitation.

The book is well printed and bound, and is very rich in excellent illustrations and diagrams.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Science in the Public Schools.

IN NATURE, vol. lxvi. p. 320, I directed attention to the insignificant place which science still holds in comparison with languages in our secondary education, as indicated by the results of the last matriculation examination at the University of London, the term "science" being limited to the sciences of experiment and observation, as distinguished from mathematical science. It was recognised at the time that the majority of the great public schools of England were only slightly represented in that examination. We have now, however, the results recently published of the examination for higher certificates conducted by the Oxford and Cambridge Schools Examination Board, which is a far better index of the real position of science in schools of the class mentioned. An examination of these lists is not found to be very reassuring. Eton College, for example, with its thousand boys, gains forty-five certificates, yet I cannot find a single name of an Eton boy who has passed in any scientific subject. The following list (with results) contains six of the largest and most representative of such schools:—

Eton ...	... 45	certificates	... 0	passes in	science.
Winchester ...	48	,,	... 4	,,	,,
Rugby ...	58	,,	... 6	,,	,,
Cheltenham College ...	32	,,	... 7	,,	,,
Clifton College	23	,,	... 8	,,	,,
Marlborough	18	,,	... 4	,,	,,

The case of Rugby is the more remarkable, since in the '70's we looked upon that school as a pioneer, the importance of science teaching having been recognised by its great head-master, Dr. Temple, now Primate of All England. It is only fair to state that several of the great public schools, such as Harrow, Wellington and Charterhouse, are not represented.

If we turn now to the published analysis of the results of the whole examination for all the schools concerned, we find 2844 passes in the four languages Latin, Greek, French and German, with 160 (or 5·6 per cent.) first classes; while for the five branches of science allowed by the Board we find only 422 passes, with 98 (or 23·2 per cent.) first classes. These figures again tell us of the great preponderance of language teaching estimated numerically; on the other hand, a comparison of the percentages of first classes is highly complimentary to the science-teaching, where it is allowed free quarter.

Speaking generally, the figures quoted may be fairly taken as representing the general attitude towards science of those who have charge of the education of the majority of the boys drawn from the best blood of England. They suggest (1) that the superstition that science forms no part of the education of a gentleman still holds the field; and (2) that the real study of science involves too much trouble in places where the interest in games dominates the whole school-life. There is not a doubt that the state of things disclosed would be to a large extent remedied if the Universities would insist upon an elementary knowledge of some one branch of science for a pass degree and the Army entrance examinations were so adjusted as to require every candidate to take up at least one science subject in the competitive examinations. The present movement in a circle leads us nowhere, with the supineness of the governing bodies of the public schools. The published results of the Army competitions do not enable us to extend the above investigation to them, since they do not tell us from what schools the several successful candidates come; but it is to be feared that even at Woolwich there is still truth in what was said to me a few years ago by one who knew, that science is looked upon as something "less than the fifth wheel of the coach"; while in the entrance examination for the Staff College, science has still, I believe, no place at all. Thus we go on dreaming, while Germany, America and other countries are wide awake, and the first rule with our leading statesmen seems to be to "shift responsibility," as they cast about them in their feeble attempts at educational legislation for "light and leading." The universities and the War Office have the power, if only they had the will, to act in the way here suggested; and it can scarcely be doubted that a speedy reform in our secondary education would come about simply through the transfer (in the magisterial mind) of science from the category of things to be *tolerated* to the category of *educational essentials.*

An experience of public-school work extending over more than a quarter of a century entitles me, I think, to venture to express strong views on this matter, which is one of natural and imperial concern. Surely, those of our scientific giants who have places on the governing bodies of our public schools might wake up to their responsibilities, look into things more closely, and do something to strengthen the hands of those who, as science masters, often labour under grave disadvantages in the stress of the conflict of interests, which must be found in every corporate society such as a great public school. There are, however, to my knowledge cases of enlightened head-masters struggling to move their governing bodies to the necessary expenditure, though insufficiently supported by the pressure of public opinion from the outside. As things are in this country, it seems hopeless to look to the "Conference of Head-Masters" (a sort of educational Vatican Council) for a broad and fair-minded dealing with this question.

This letter is not written in any spirit of hostility to classical and literary studies, the culture derived from which is too often lacking among men of science, but under the conviction that, with a keener spirit of *work* in the public schools and a better correlation and graduation of studies, science might lift up its head more than it does at present. A. IRVING.

Bishop's Stortford, September 3.

Animal Intelligence.

ALTHOUGH the terms "ass" and, at any rate in Germany, "ox" (*Ochs*) are very generally applied to stupid persons, those who have observed the bovine and asinine genera know that this is an injustice to those animals; and the following instances of particular intelligence displayed by two of the thus maligned beasts seem worth recording.

A donkey that was kept here learnt to open, not only the gate of its own field, but other gates. One day, having left its own abode, accompanied by two ponies, it went to another field half a mile off, opening three gates on the way, liberated the occupants of this field, a mare and her foal, and a yearling, old friends of the donkey's, as they used to live together, and the whole party, which had been joined by a mastiff, proceeded to wander through the world. About two miles from here the horses were recognised and secured, and the donkey eventually returned with the mastiff; but after this exploit it was thought advisable to get rid of the donkey, as being too zealously devoted to the cause of emancipation.

A Scotch bullock, which had been in the park here for about two years, was sold to a butcher at Derby Market (fourteen miles south of this place) and taken by train to Darley (nine miles north of here). A day or two afterwards the bullock found its way back here, having escaped from its would-be slaughterer, but had, alas! to be sent back to him. It is incredible that the animal can have observed the road from the railway, and the only explanation is that it was brought along the road from Darley when driven here originally from Scotland; but in any case this is a striking instance of tenacious memory and strong attachment to home or comrades.

L. C. HURT.

Alderwasley, Matlock, Derbyshire, September 4.

Variation of Common Copper Butterfly.

IN August, I took a rather large specimen of *Polymatus phloeas* (the common copper butterfly), which has a row of four faint silver-blue spots inside the copper band on the posterior margin of the upper surface of the hind wings.

I should be very glad if any of your readers could tell me if this variation is common, as I can find no mention of it in the book I use, and have never seen another case, though I have examined many of the same species.

With apologies for troubling you. PH. T.

SOME SCIENTIFIC CENTRES.

V.—The Chemical Laboratory of the Royal Institution.

THE record of the chemical laboratory of the Royal Institution is such as to give it an unique position among laboratories. The Royal Institution was established in Albemarle Street, London, in 1800, and had its origin in the work Count Rumford did for the poor at Munich—in fact, it first came into existence, in 1799, as the Rumford Institution. We are told that "its primary objects were models, workshops, and useful knowledge to benefit the poor; and that lectures, researches and scientific experiments to amuse and interest the rich, and to advance science, were comparatively the secondary intention of its founder"—and yet the advancement of science has always been its chief function, and it is safe to say that no other single institution has so brilliant a record of successes. But we have only to think of Davy's invention of the safety lamp and of Faraday's electrical researches—of which the modern dynamo and electric traction are an outcome—to realise that, as a matter of fact, the researches carried out in the laboratory of the Institution have served, in the most direct manner possible, to benefit the poor and to carry out Rumford's true purpose, and this, too, in a manner and with a completeness which he could never have contemplated as in the least degree possible. It has proved to be, not merely "a public institution for diffusing the knowledge and facilitating the general introduction of useful mechanical inventions and improvements"—but the birthplace of discoveries which have given rise to them.

Writing from the Royal Institution to his daughter in March, 1801, Rumford said:—"We have found a nice able man for this place as lecturer [on chemistry], Humphrey Davy." A few years later he was able to speak of Davy as the man "who by his eloquence and genius saved the Rumford Institution from an early death." Davy did far more than lecture—from the outset he gave to the Institution its policy, by making it the home of research, and set an example of which it is impossible to exaggerate the importance. Davy was appointed in February, 1801. Volta had just made his great discovery; as Davy phrases it, "the voltaic battery was an alarm bell to experimenters in every part of Europe." Nicholson and Carlisle made the discovery of the decomposition of water by the pile on April 30, 1800. Davy was at once attracted to the study of galvanism, and he treated of galvanic phenomena in his first course of lectures. The closing paragraph of the series of extracts from this course, published in vol. i. of the *Journal* of the Royal Institution under the date September 1, 1801, is a happy forecast of the victories to be won by himself and others in the field of galvanism:—

"But independent of the immediate applications of this science, much is to be hoped from the elucidations which it may bestow upon the kindred sciences. And a discovery so important as to excite our astonishment cannot fail of becoming at some period useful to society. All the different branches of human knowledge are intimately connected together, and theoretical improvements cannot well be made in them without being accompanied by practical advantages."

Davy's initial triumph in this field was won in 1806, when he delivered the Bakerian lecture, "On some Chemical Agencies of Electricity." The fact that the Institute of France awarded him for this the prize founded by Napoleon for the most important discovery in galvanism, at a time when England and France were at war, is clear proof of the importance attached to his work by the scientific opinion of the time. In the following year came the great discovery of the alkali metals which immortalised his name. It is fair to say that previous workers had made but chance discoveries, but that Davy's work was clearly based on theory; in fact, that it laid the first theoretical foundations of electrochemical science. Davy laid great stress on the interdependence of chemical and electrical phenomena. Faraday, his successor, fully established by his researches their quantitative interrelationship, and formulated the laws which to the present day serve to guide us. The importance of these researches to chemical theory was dwelt on by Helmholtz, in 1881, in the Faraday memorial lecture which he delivered to the fellows of the Chemical Society in the theatre of the Royal Institution. The conception of valency as consequent on atomic charges of electricity deduced from Faraday's researches, to which Helmholtz directed attention, has yet to be fully appreciated. The closing years of the century, we know, witnessed a remarkable development of electrochemical theory at the hands of Arrhenius and Van 't Hoff; whether the hypothesis applied by these two philosophers be essentially true or not matters little—it is sufficient that it has made the mathematical discussion of chemical phenomena possible, with a degree of accuracy and to an extent altogether remarkable. Modern electrochemical theory, however, is largely based on the discoveries made in the chemical laboratory of the Royal Institution, and this may well be regarded as the original home of both pure and applied electrochemical science.

Davy was both professor of chemistry and director of the laboratory; when Brande followed him as professor, Faraday became director of the laboratory and later on Fullerian professor of chemistry. Faraday's chemical work has never been sufficiently appreciated, his electrical researches having overshadowed it. The skill displayed in his organic researches would do credit to a well-trained chemist at the present day—and yet he was self-trained in such work and there were no precedents to guide him. From this point of view, on account of its completeness, the memoir in which the discovery of benzene was described by him in 1825 is altogether remarkable. The modern chemist thinks only of Kekulé in connection with benzene, but if the hexagon be the appropriate symbol to put on the shield of Kekulé's memory, its shadow should at least hover in the atmosphere of the Royal Institution laboratory—especially as the present occupant of the Fullerian chair has won the right to have it put on his hatchment with nitrogen substituted for carbon at one of the angles. In discovering benzene, Faraday laid the foundation-stone of the coal-tar colour industry. A second most important contribution to this industry was made by him in 1826 by the discovery of sulphonaphthalic acid. We rarely think of him as the father of sulphonic acids, or as the progenitor of the naphthols and the madder colours. No one would have rejoiced more than Faraday over a wondrous story such as can now be told of benzene—of the manner in which a large part of organic chemistry centres around it, and of the way in which with its aid the colour-producing power of Nature has been altogether outdone.

Faraday's work on the condensation of the gases will always stand unrivalled on account of the originality and simplicity of his methods and of its completeness; its influence, we know, has been world-wide.

At the beginning of his career at the Royal Institution, Davy turned his attention to agricultural chemistry. He was in consequence engaged by the Board of Agriculture, in 1802, to deliver a course of lectures to its members on the connection of chemistry with vegetable physiology. This he continued to do for ten years, and he thus laid the foundation of agricultural science in this country. Had so wise a proceeding been continued, agriculture might well have been in a far better position than it now is.

Faraday also had technical proclivities, as shown by

his researches on the alloys of steel and on the manufacture of optical glass. Had the example he set in the Royal Institution laboratory been followed, we should scarcely now be making the armour plates for our iron clads under license from Krupp, or be obliged to resort to Jena for improved qualities of glass.

Brande, who occupied the chair in succession to Davy, from 1813 to 1852, did little in the way of research work. Faraday's star was brightest throughout most of these years, and it would indeed have been remarkable had there been a second chemical luminary. It was during Brande's time that the attempt was made to establish a school of chemistry at the Institution which the late Sir F. Abel referred to in the Hofmann memorial lecture as the movement which culminated in the foundation of the Royal College of Chemistry.

Prof. James Dewar, F.R.S.

Frankland, who held the professorship of chemistry from 1863 to 1868, did some of his best work in the Institution laboratory, notably the research (in conjunction with Duppa) on the action of sodium (followed by that of methyl or ethyl iodide) on acetic ether, which has since proved to be one of the most fruitful of synthetic methods. In the course of lectures on coal gas which he delivered in 1867—fully reported at the time in the *Journal of Gas Lighting*, but not otherwise published—he advanced novel views on the origin of flame which have not yet received the consideration they deserve. In extension of this inquiry, he was led to investigate the influence of pressure on the emission of light; among the important results he obtained was the observation that a considerable luminous effect was obtained by burning hydrogen in oxygen under pressure.

Prof. Dewar was appointed Fullerian professor in 1877. Those who have followed his career may recall the two Friday evening lectures he gave prior to his appointment, describing work which he and Prof. McKendrick had done on the effect of light on the retina and optic nerve; the latter of these especially was a remarkable *tour de force*, exhibiting the facility of experimental resource and brilliance of demonstration which have ever since characterised Prof. Dewar's lectures and rendered them so peculiarly attractive and instructive. It should not be forgotten that he was the first to study the oxidation products of the quinoline bases. His earlier work at the Institution lay in a field far removed from that in which he has since acquired such distinction, and was carried out at high temperatures. The reversibility of the rays of metallic vapours, the origin and identification of spectra, and the synthetic changes effected in the electric arc occupied his attention at this time. Much of this work was done in conjunction with Prof. Liveing. Prof. Dewar entered the field of low-temperature research in the early eighties, and gradually the chemical laboratory of the Royal Institution has been transformed into a veritable machine shop. For years past liquid air has been handled there as though it were water, and researches have been systematically carried on at very low temperatures with the certainty and ease with which experiments are made in laboratories generally at ordinary temperatures. Our knowledge of the properties of matter at temperatures near to the absolute zero has consequently been developed to a remarkable extent. To quote the words used by the President of the Royal Society in 1894, with reference to his work on the liquefaction of gases, when handing to him the Rumford medal, Prof. Dewar "has displayed, not only marvellous manipulative skill and fertility of resource, but also great personal courage, such researches being attended with considerable danger. One of his chief objects has been so to improve and develop the methods of liquefying the more permanent gases that it shall become possible to deal with large quantities of liquid, and to use such liquids as instruments of research in extending our knowledge of the general behaviour of substances at very low temperatures. In this he has already been highly successful. Not only has he succeeded in preparing large quantities of liquid oxygen, but he has been able by the device of vacuum-jacketed vessels to store this liquid under atmospheric pressure during long intervals, and thus to use it as a cooling agent."

The vacuum vessels here referred to were introduced into use by Prof. Dewar in 1892, and have contributed in an extraordinary degree to the advancement of research

at low temperatures. Without them, the crowning achievement of obtaining hydrogen in the liquid state (May, 1898) would scarcely have been possible. Prof. Dewar is shown handling one of these vessels in the picture on p. 461.

The researches carried out under the transcendental conditions now available at the Royal Institution have led to many surprises: notably is this true of the investigations carried out by Profs. Dewar and Fleming on the electrical conductivity of metals, and on specific inductive capacity. The fact that almost all substances may be rendered phosphorescent by insolation when cooled to low temperatures is another discovery made by Prof. Dewar which promises to be of special importance in the light of recent researches on radio-activity.

But to understand Prof. Dewar fully, it is necessary to know him in the upper as well as in the lower regions of the Royal Institution; not only the wealth of his powers of imagination and his scientific acumen then become apparent, but it is realised that he is a man of extraordinarily sympathetic nature, penetrated with artistic feeling and emotions. Unfortunately, he is also gifted with a reticence rare among artists, which is particularly manifest when the time comes to commit his thoughts to paper; the world has lost much in not being made fully acquainted with his discoveries, and if his reflections were more frequently uttered outside his private circle, it would be to the advantage of scientific progress. We may hope that there is much time left to him in which to repair minor faults such as these.

A laboratory in which so many remarkable and important discoveries have been made may certainly be said to have justified the hopes of its founder, and it is surprising that its successes have not won for it a larger measure of public support—that as yet it has had no imitators.

But there is one respect in which Count Rumford might well deplore failure. However much the lectures delivered in the Institution may have interested and even amused the rich, they have failed to lead them to appreciate in any proper measure the value of scientific research to the nation, a subject on which Davy dwelt much in his lectures; for had they done so, an industry such as the coal-tar colour industry, so closely connected in its origin with the Institution, which was first established and for a time flourished in this country, would not have been allowed to pass almost entirely into other hands; the attempt made by Davy to raise agriculture to a science would have been persevered in at the public cost; electrochemistry would have been steadily developed; and pioneer work such as Faraday did on iron and glass would not have been allowed to stand in splendid isolation. A century of the highest example has had little effect in making the knowledge of scientific method a public possession.

THE BELFAST MEETING OF THE BRITISH ASSOCIATION.

In previous issues of NATURE, particulars have been given as to the local arrangements which have been made for the comfort of those attending this meeting, and the titles of the papers which may be expected to be read in the various sections have been published; not much remains, therefore, to be said by us on this occasion. It may, however, be stated that the illustrated handbook or guide issued by the Association and prepared under the auspices of the Belfast Naturalists' Field Club appears to have been very carefully compiled. It deals with the subjects respectively of Belfast, geology, botany, zoology and antiquities, and is the work of many writers. So far as can be seen as we go to press, the meeting will be a successful one, it being estimated that in point of numbers attending it will equal the gathering of 1874, at which the total attendance was 1951. Given fine weather, the meeting should be no less enjoyable and interesting than many of its predecessors. It had been hoped that the *Scotia*, of the Scottish Antarctic Expedition, would have been able to visit the harbour and be open for inspection by the members of the Association; this hope, however, seems likely to be disappointed. The address of the President, Prof. Dewar, was delivered as we went to press yesterday, and the various sections began their proceedings this morning. In this issue we print the Presidential Address and that of the President of Section A. Other addresses and accounts of the papers and reports brought before the sections will duly appear in subsequent numbers.

INAUGURAL ADDRESS BY PROF. JAMES DEWAR, M.A., LL.D., D.SC., F.R.S., PRESIDENT OF THE ASSOCIATION.

THE members of an Association whose studies involve perpetual contemplation of settled law and ordered evolution, whose objects are to seek patiently for the truth of things and to extend the dominion of man over the forces of nature, are even more deeply pledged than other men to loyalty to the Crown and the Constitution which procure for them the essential conditions of calm security and social stability. I am confident that I express the sentiments of all now before me when I say that to our loyal respect for his high office we add a warmer feeling of loyalty and attachment to the person of our Gracious Sovereign. It is the peculiar felicity of the British Association that, since its foundation seventy-one years ago, it has always been easy and natural to cherish both these sentiments, which indeed can never be dissociated without peril. At this, our second meeting held under the present reign, these sentiments are realised all the more vividly, because, in common with the whole empire, we have recently passed through a period of acute apprehension, followed by the uplifting of a national deliverance. The splendid and imposing coronation ceremony which took place just a month ago was rendered doubly impressive both for the King and his people by the universal consciousness that it was also a service of thanksgiving for escape from imminent peril. In offering to His Majesty our most hearty congratulations upon his singularly rapid recovery from a dangerous illness, we rejoice to think that the nation has received gratifying evidence of the vigour of his constitution, and may, with confidence more assured than before, pray that he may have length of happy and prosperous days. No one in his wide dominions is more competent than the King to realise how much he owes, not only to the skill of his surgeons, but also to the equipment which has been placed in their hands as the combined result of scientific investigation in many and diverse directions. He has already displayed a profound and sagacious interest in the discovery of methods for dealing with some of the most intractable maladies that still baffle scientific penetration; nor can we doubt that this interest extends to other forms of scientific investigation, more directly connected with the amelioration of the lot of the healthy than with the relief of the sick. Heredity imposes obligations and also confers aptitude for their discharge. If His Majesty's royal mother throughout her long and beneficent reign set him a splendid example of devotion to the burdensome labours of State which must necessarily absorb the chief part of his energies, his father no less clearly indicated the great part he may play in the encouragement of science. Intelligent appreciation of scientific work and needs is not less but more necessary in the highest quarters to-day than it was forty-three years ago, when His Royal Highness the Prince Consort brought the matter before this Association in the following memorable passage in his Presidential Address: "We may be justified, however, in hoping that by the gradual diffusion of science and its increasing recognition as a principal part of our national education, the public in general, no less than the legislature and the State, will more and more recognise the claims of science to their attention; so that it may no longer require the begging box, but speak to the State like a favoured child to its parent, sure of its paternal solicitude for its welfare; that the State will recognise in science one of its elements of strength and prosperity, to protect which the clearest dictates of self-interest demand." Had this advice been seriously taken to heart and acted upon by the rulers of the nation at the time, what splendid

results would have accrued to this country! We should not now be painfully groping in the dark after a system of national education. We should not be wasting money, and time more valuable than money, in building imitations of foreign educational superstructures before having put in solid foundations. We should not be hurriedly and distractedly casting about for a system of tactics after confrontation with the disciplined and co-ordinated forces of industry and science led and directed by the rulers of powerful States. Forty-three years ago we should have started fair had the Prince Consort's views prevailed. As it is, we have lost ground which it will tax even this nation's splendid reserves of individual initiative to recover. Although in this country the king rules, but does not govern, the Constitution and the structure of English society assure to him a very potent and far-reaching influence upon those who do govern. It is hardly possible to overrate the benefits that may accrue from his intelligent and continuous interest in the great problem of transforming his people into a scientifically educated nation. From this point of view we may congratulate ourselves that the heir to the Crown, following his family traditions, has already deduced from his own observations in different parts of the empire some very sound and valuable conclusions as to the national needs at the present day.

Griffith—Gilbert—Cornu.

The saddest yet the most sacred duty falling to us on such an occasion as the present is to pay our tribute to the memory of old comrades and fellow-workers whom we shall meet no more. We miss to-day a figure that has been familiar, conspicuous, and always congenial at the meetings of the British Association during the last forty years. Throughout the greater part of that period Mr. George Griffith discharged the onerous and often delicate duties of the assistant general secretary, not only with conscientious thoroughness and great ability, but also with urbanity, tact and courtesy that endeared him to all. His years sat lightly upon him, and his undiminished alertness and vigour caused his sudden death to come upon us all with a shock of surprise as well as of pain and grief. The British Association owes him a debt of gratitude which must be so fully realised by every regular attender of our meetings that no poor words of mine are needed to quicken your sense of loss, or to add to the poignancy of your regret.

The British Association has to deplore the loss from among us of Sir Joseph Gilbert, a veteran who continued to the end of a long life to pursue his important and beneficent researches with untiring energy. The length of his services in the cause of science cannot be better indicated than by recalling the fact that he was one of the six past Presidents boasting fifty years' membership whose jubilee was celebrated by the Chemical Society in 1898. He was in fact an active member of that Society for over sixty years. Early in his career he devoted himself to a most important but at that time little cultivated field of research. He strove with conspicuous success to place the oldest of industries on a scientific basis, and to submit the complex conditions of agriculture to a systematic analysis. He studied the physiology of plant life in the open air, not with the object of penetrating the secrets of structure, but with the more directly utilitarian aim of establishing the conditions of successful and profitable cultivation. By a long series of experiments, alike well conceived and laboriously carried out, he determined the effects of variation in soil, and its chemical treatment—in short, in all the unknown factors with which the farmer previously had to deal according to empirical and local rules, roughly deduced from undigested experience by uncritical and rudimentary processes of inference. Gilbert had the faith, the insight and the courage to devote his life to an investigation so difficult, so unpromising, and so unlikely to bring the rich rewards attainable by equal diligence in other directions, as to offer no attraction to the majority of men. The tabulated results of the Rothamsted experiments remain as a benefaction to mankind and a monument of indomitable and disinterested perseverance.

It is impossible for me in this place to offer more than the barest indication of the great place in contemporary science that has been vacated by the lamented death of Prof. Alfred Cornu, who so worthily upheld the best traditions of scientific France. He was gifted in a high degree with the intellectual lucidity, the mastery of form and the perspicuous method which characterise the best exponents of French thought in all departments of study. After a brilliant career as a student, he was chosen at the early age of twenty-six to fill one of the enviable positions more numerous in Paris than in London, the Professorship of Physics at the École Polytechnique. In that post, which he occupied to the end of his life, he found what is probably the ideal combination for a man of science—leisure and material equipment for original research, together with that close and stimulating contact with practical affairs afforded by his duties as teacher in a great school, almost ranking as a department of State. Cornu was admirable alike in the use he made of his opportunities and in his manner of discharging his duties. He was at once a great investigator and a great teacher. I shall not even attempt a summary, which at the best must be very imperfect, of his brilliant achievements in optics, the study of his predilection, in electricity, in acoustics and in the field of physics generally. As a proof of the great estimation in which he was held, it is sufficient to remind you that he had filled the highest presidential offices in French scientific societies, and that he was a foreign member of our Royal Society and a recipient of its Rumford medal. In this country he had many friends, attracted no less by his personal and social qualities than by his commanding abilities. Some of those here present may remember his appearance a few years ago at the Royal Institution, and more recently his delivery of the Rede Lecture at Cambridge, when the University conferred upon him the honorary degree of Doctor of Science. His death has inflicted a heavy blow upon our generation, upon France and upon the world.

The Progress of Belfast.

A great man has observed that the "intelligent anticipation of events before they occur" is a factor of some importance in human affairs. One may suppose that intelligent anticipation had something to do with the choice of Belfast as the meeting-place of the British Association this year. Or, if it had not, then it must be admitted that circumstances have conspired, as they occasionally do, to render the actual selection peculiarly felicitous. Belfast has perennial claims, of a kind that cannot easily be surpassed, to be the scene of a great scientific gathering—claims founded upon its scientific traditions and upon the conspicuous energy and success with which its citizens have prosecuted in various directions the application of science to the purposes of life. It is but the other day that the whole nation deplored at the grave of Lord Dufferin the loss of one of the most distinguished and most versatile public servants of the age. That great statesman and near neighbour of Belfast was a typical expression of the qualities and the spirit which have made Belfast what it is, and have enabled Ireland, in spite of all drawbacks, to play a great part in the Empire. I look round on your thriving and progressive city giving evidence of an enormous aggregate of industrial efforts intelligently organised and directed for the building up of a sound social fabric. I find that your great industries are interlinked and interwoven with the whole economic framework of the Empire, and that you are silently and irresistibly compelled to harmonious cooperation by practical considerations acting upon the whole community. It is here that I look for the real Ireland, the Ireland of the future. We cannot trace with precision the laws that govern the appearance of eminent men, but we may at least learn from history that they do not spring from every soil. They do not appear among decadent races or in ages of retrogression. They are the fine flower of the practical intellect of the nation working studiously and patiently in accordance with the great laws of conduct. In the manifold activities of Belfast we have a splendid manifestation of individual energy working necessarily, even if not altogether consciously, for the national good. In great Irishmen like Lord Dufferin and Lord Roberts, giving their best energies for the defence of the nation by diplomacy or by war, we have complementary evidence enough to reassure the most timid concerning the real direction of Irish energies and the vital nature of Irish solidarity with the rest of the Empire.

Belfast has played a prominent part in a transaction of a somewhat special and significant kind, which has proved not a little confusing and startling to the easy-going public. The significance of the shipping combination lies in the light it throws on the conditions and tendencies which make such things possible, if not even inevitable. It is an event forcibly illustrating the declaration of His Royal Highness the Prince of Wales, that the nation must "wake up" if it hopes to face its growing responsibilities. Belfast may plead with some justice that it, at least, has never gone to sleep. In various directions an immense advance has been effected during the

twenty-eight years that have elapsed since the last visit of the British Association. Belfast has become first a city and then a county, and now ranks as one of the eight largest cities in the United Kingdom. Its municipal area has been considerably extended, and its population has increased by something like 75 per cent. It has not only been extended, but improved and beautified in a manner which very few places can match, and which probably none can surpass. Fine new thoroughfares, adorned with admirable public institutions, have been run through areas once covered with crowded and squalid buildings. Compared with the early fifties, when iron shipbuilding was begun on a very modest scale, the customs collected at the port have increased tenfold. Since the introduction of the power-loom, about 1850, Belfast has distanced all rivals in the linen industry, which continues to flourish notwithstanding the fact that most of the raw material is now imported, instead of being produced, as in former times, in Ulster. Extensive improvements have been carried out in the port at a cost of several millions, and have been fully justified by a very great expansion of trade. These few bare facts suffice to indicate broadly the immense strides taken by Belfast in the last two decades. For an Association that exists for the advancement of science it is stimulating and encouraging to find itself in the midst of a vigorous community, successfully applying knowledge to the ultimate purpose of all human effort, the amelioration of the common lot by an ever-increasing mastery of the powers and resources of Nature.

Tyndall and Evolution.

The Presidential Address delivered by Tyndall in this city twenty-eight years ago will always rank as an epoch-making deliverance. Of all the men of the time, Tyndall was one of the best equipped for the presentation of a vast and complicated scientific subject to the mass of his fellow-men. Gifted with the powers of a many-sided original investigator, he had at the same time devoted much of his time to an earnest study of philosophy, and his literary and oratorical powers, coupled with a fine poetic instinct, were qualifications which placed him in the front rank of the scientific representatives of the later Victorian epoch, and constituted him an exceptionally endowed exponent of scientific thought. In the Belfast discourse Tyndall dealt with the changing aspects of the long unsettled horizon of human thought, at last illuminated by the sunrise of the doctrine of evolution. The consummate art with which he marshalled his scientific forces for the purpose of effecting conviction of the general truth of the doctrine has rarely been surpassed. The courage, the lucidity, the grasp of principles, the moral enthusiasm with which he treated his great theme have powerfully aided in effecting a great intellectual conquest, and the victory assuredly ought to engender no regrets.

Tyndall's views as a strenuous supporter and believer in the theory of evolution were naturally essentially optimistic. He had no sympathy with the lugubrious pessimistic philosophy whose disciples are for ever intent on administering rebuke to scientific workers by reminding them that, however much knowledge man may have acquired, it is as nothing compared with the immensity of his ignorance. That truth is indeed never adequately realised except by the man of science, to whom it is brought home by repeated experience of the fact that his most promising excursions into the unknown are invariably terminated by barriers which, for the time at least, are insurmountable. He who has never made such excursions with patient labour may indeed prattle about the vastness of the unknown, but he does so without real sincerity or intimate conviction. His tacit, if not his avowed, contention is, that since we can never know all it is not worth while to seek to know more; and that in the profundity of his ignorance he has the right to people the unexplored spaces with the phantoms of his vain imagining. The man of science, on the contrary, finds in the extent of his ignorance a perpetual incentive to further exertion, and in the mysteries that surround him a continual invitation, nay, more, an inexorable mandate. Tyndall's writings abundantly prove that he had faced the great problems of man's existence with that calm intellectual courage the lack of which goes very far to explain the nervous dogmatism of nescience. Just because he had done this, because he had, as it were, mapped out the boundaries between what is knowable though not yet known and what must remain for ever unknowable to man, he did not hesitate to place implicit reliance on the progress of which man is capable, through the exercise of patient and persistent research.

In Tyndall's scheme of thought the chief dicta were the strict division of the world of knowledge from that of emotion, and the lifting of life by throwing overboard the malign residuum of dogmatism, fanaticism, and intolerance, thereby stimulating and nourishing a plastic vigour of intellect. His cry was "Commotion before stagnation, the leap of the torrent before the stillness of the swamp."

His successors have no longer any need to repeat those significant words, "We claim and we shall wrest from theology the entire domain of cosmological theory." The claim has been practically, though often unconsciously, conceded. Tyndall's dictum, "Every system must be plastic to the extent that the growth of knowledge demands," struck a note that was too often absent from the heated discussions of days that now seem so strangely remote. His honourable admission that, after all that had been achieved by the developmental theory, "the whole process of evolution is the manifestation of a power absolutely inscrutable to the intellect of man," shows how willingly he acknowledged the necessary limits of scientific inquiry. This reservation did not prevent him from expressing the conviction forced upon him by the pressure of intellectual necessity, after exhaustive consideration of the known relations of living things, that matter in itself must be regarded as containing the promise and potency of all terrestrial life. Bacon in his day said very much the same thing: "He that will know the properties and proceedings of matter should comprehend in his understanding the sum of all things, which have been, which are, and which shall be, although no knowledge can extend so far as to singular and individual beings." Tyndall's conclusion was at the time thought to be based on a too insecure projection into the unknown, and some even regarded such an expansion of the crude properties of matter as totally unwarranted. Yet Tyndall was certainly no materialist in the ordinary acceptation of the term. It is true his arguments, like all arguments, were capable of being distorted, especially when taken out of their context, and the address became in this way an easy prey for hostile criticism. The glowing rhetoric that gave charm to his discourse and the poetic similes that clothed the dry bones of his close-woven logic were attacked by a veritable broadside of critical artillery. At the present day these would be considered as only appropriate artistic embellishments, so great is the unconscious change wrought in our surroundings. It must be remembered that, while Tyndall discussed the evolutionary problem from many points of view, he took up the position of a practical disciple of Nature dealing with the known experimental and observational realities of physical inquiry. Thus he accepted as fundamental concepts the atomic theory, together with the capacity of the atom to be the vehicle or repository of energy, and the grand generalisation of the conservation of energy. Without the former, Tyndall doubted whether it would be possible to frame a theory of the material universe; and as to the latter he recognised its radical significance in that the ultimate philosophical issues therein involved were as yet but dimly seen. That such generalisations are provisionally accepted does not mean that science is not alive to the possibility that what may now be regarded as fundamental may in future be superseded or absorbed by a wider generalisation. It is only the poverty of language and the necessity for compendious expression that oblige the man of science to resort to metaphor and to speak of the Laws of Nature. In reality, he does not pretend to formulate any laws for Nature, since to do so would be to assume a knowledge of the inscrutable cause from which alone such laws could emanate. When he speaks of a "law of Nature" he simply indicates a sequence of events which, so far as his experience goes, is invariable, and which therefore enables him to predict, to a certain extent, what will happen in given circumstances. But, however seemingly bold may be the speculation in which he permits himself to indulge, he does not claim for his best hypothesis more than provisional validity. He does not forget that to-morrow may bring a new experience compelling him to recast the hypothesis of to-day. This plasticity of scientific thought, depending upon reverent recognition of the vastness of the unknown, is oddly made a matter of reproach by the very people who harp upon the limitations of human knowledge. Yet the essential condition of progress is that we should generalise to the best of our ability from the experience at command, treat our theory as provisionally true, endeavour to the best of our power to reconcile with it all the new facts we discover, and abandon or modify it when it ceases to afford a coherent explanation of new experience. That procedure is far

as are the poles asunder from the presumptuous attempt to travel beyond the study of secondary causes. Any discussion as to whether matter or energy was the true reality would have appeared to Tyndall as a futile metaphysical disputation which, being completely dissociated from verified experience, would lead to nothing. No explanation was attempted by him of the origin of the bodies we call elements, nor how some of such bodies came to be compounded into complex groupings and built up into special structures with which, so far as we know, the phenomena characteristic of life are invariably associated. The evolutionary doctrine leads us to the conclusion that life, such as we know it, has only been possible during a short period of the world's history, and seems equally destined to disappear in the remote future; but it postulates the existence of a material universe endowed with an infinity of powers and properties, the origin of which it does not pretend to account for. The enigma at both ends of the scale Tyndall admitted, and the futility of attempting to answer such questions he fully recognised. Nevertheless, Tyndall did not mean that the man of science should be debarred from speculating as to the possible nature of the simplest forms of matter or the mode in which life may have originated on this planet. Lord Kelvin, in his Presidential Address, put the position admirably when he said "Science is bound by the everlasting law of honour to face fearlessly every problem that can fairly be presented to it. If a probable solution consistent with the ordinary course of Nature can be found, we must not invoke an abnormal act of Creative Power"; and in illustration he forthwith proceeded to express his conviction that from time immemorial many worlds of life besides our own have existed, and that "it is not an unscientific hypothesis that life originated on this earth through the moss-grown fragments from the ruins of another world." In spite of the great progress made in science, it is curious to notice the occasional recrudescence of metaphysical dogma. For instance, there is a school which does not hesitate to revive ancient mystifications in order to show that matter and energy can be shattered by philosophical arguments, and have no objective reality. Science is at once more humble and more reverent. She confesses her ignorance of the ultimate nature of matter, of the ultimate nature of energy, and still more of the origin and ultimate synthesis of the two. She is content with her patient investigation of secondary causes, and glad to know that since Tyndall spoke in Belfast she has made great additions to the knowledge of general molecular mechanism, and especially of synthetic artifice in the domain of organic chemistry, though the more exhaustive acquaintance gained only forces us the more to acquiesce in acknowledging the inscrutable mystery of matter. Our conception of the power and potency of matter has grown in little more than a quarter of a century to much more imposing dimensions, and the outlook for the future assuredly suggests the increasing acceleration of our rate of progress. For the impetus he gave to scientific work and thought, and for his fine series of researches chiefly directed to what Newton called the more secret and noble works of Nature within the corpuscles, the world owes Tyndall a debt of gratitude. It is well that his memory should be held in perennial respect, especially in the land of his birth.

The Endowment of Education.

These are days of munificent benefactions to science and education, which, however, are greater and more numerous in other countries than in our own. Splendid as they are, it may be doubted, if we take into account the change in the value of money, the enormous increase of population and the utility of science to the builders of colossal fortunes, whether they bear comparison with the efforts of earlier days. But the habit of endowing science was so long in practical abeyance that every evidence of its resumption is matter for sincere congratulation. Mr. Cecil Rhodes has dedicated a very large sum of money to the advancement of education, though the means he has chosen are perhaps not the most effective. It must be remembered that his aims were political as much as educational. He had the noble and worthy ambition to promote enduring friendship between the great English-speaking communities of the world, and knowing the strength of college ties he conceived that this end might be greatly furthered by bringing together at an English university the men who would presumably have much to do in later life with the influencing of opinion, or even with the direction of policy. It has been held by some a striking tribute to Oxford that a man but little given to academic pursuits or modes of thought should think it a matter of high importance to bring men from our colonies or even from Germany, to submit to the formative influences of that ancient seat of learning. But this is perhaps reading Mr. Rhodes backwards. He showed his affectionate recollection of his college days by his gift to Oriel. But, apart from the main idea of fostering good relations between those who will presumably be influential in England, in the colonies, and in the United States, Mr. Rhodes was probably influenced also by the hope that the influx of strangers would help to broaden Oxford notions and to procure revision of conventional arrangements.

Dr. Andrew Carnegie's endowment of Scottish universities, as modified by him in deference to expert advice, is a more direct benefit to the higher education. For while Mr. Rhodes has only enabled young men to get what Oxford has to give, Dr. Carnegie has also enabled his trustees powerfully to augment and improve the teaching equipment of the universities themselves. At the same time, he has provided as far as possible for the enduring usefulness of his money. His trustees form a permanent body external to the universities, which, while possessing no power of direct control, must always, as holder of the purse-strings, be in a position to offer independent and weighty criticisms. More recently Dr. Carnegie has devoted an equal sum of ten million dollars to the foundation of a Carnegie Institution in Washington. Here again he has been guided by the same ideas. He has neither founded a university nor handed over the money to any existing university. He has created a permanent trust charged with the duty of watching educational efforts and helping them from the outside according to the best judgment that can be formed in the circumstances of the moment. Its aims are to be—to promote original research; to discover the exceptional man in every department of study, whether inside or outside of the schools, and to enable him to make his special study his life-work; to increase facilities for higher education; to aid and stimulate the universities and other educational institutions; to assist students who may prefer to study at Washington; and to ensure prompt publication of scientific discoveries. The general purpose of the founder is to secure, if possible, for the United States leadership in the domain of discovery and the utilisation of new forces for the benefit of man. Nothing will more powerfully further this end than attention to the injunction to lay hold of the exceptional man whenever and wherever he may be found, and, having got him, to enable him to carry on the work for which he seems specially designed. That means, I imagine, a scouring of the old world, as well as of the new, for the best men in every department of study—in fact, an assiduous collecting of brains similar to the collecting of rare books and works of art which Americans are now carrying on in so lavish a manner. As in diplomacy and war, so in science, we owe our reputation, and no small part of our prosperity, to exceptional men; and that we do not enjoy these things in fuller measure we owe to our lack of an army of well-trained ordinary men capable of utilising their ideas. Our exceptional men have too often worked in obscurity, without recognition from a public too imperfectly instructed to guess at their greatness, without assistance from a State governed largely by dialecticians, and without help from academic authorities hidebound by the pedantries of medieval scholasticism. For such men we have to wait upon the will of Heaven. Even Dr. Carnegie will not always find them when they are wanted. But what can be done in that direction will be done by institutions like Dr. Carnegie's, and for the benefit of the nation that possesses them in greatest abundance and uses them most intelligently. When contemplating these splendid endowments of learning, it occurred to me that it would be interesting to find out exactly what some definite quantity of scientific achievement has cost in hard cash. In an article by Carl Snyder in the January number of the *North American Review*, entitled "America's Inferior Place in the Scientific World," I found the statement that "it would be hardly too much to say that during the hundred years of its existence the Royal Institution alone has done more for English science than all of the English universities put together. This is certainly true with regard to British industry, for it was here that the discoveries of Faraday were made." I was emboldened by this estimate from a distant and impartial observer to do, what otherwise I might have shrunk from doing, and to take the Royal Institution—after all, the foundation of an American citizen, Count Rumford—as the basis of my inquiry. The work done

at the Royal Institution during the past hundred years is a fairly definite quantity in the mind of every man really conversant with scientific affairs. I have obtained from the books accurate statistics of the total expenditure on experimental inquiry and public demonstrations for the whole of the nineteenth century. The items are:—

	£
Professors' Salaries—Physics and Chemistry	54,600
Laboratory Expenditure	24,430
Assistants' Salaries	21,590
Total for one hundred years	£100,620

In addition, the members and friends of the Institution have contributed to a fund for exceptional expenditure for Experimental Research the sum of 9580*l.* It should also be mentioned that a Civil List Pension of 300*l.* was granted to Faraday in 1853, and was continued during twenty-seven years of active work and five years of retirement. Thirty-two years in all, at 300*l.* a year, make a sum of 9600*l.*, representing the national donation, which, added to the amount of expenditure just stated, brings up the total cost of a century of scientific work in the laboratories of the Royal Institution, together with public demonstrations, to 119,800*l.*, or an average of 1200*l.* per annum. I think if you recall the names and achievements of Young, Davy, Faraday, and Tyndall, you will come to the conclusion that the exceptional man is about the cheapest of natural products. It is a popular fallacy that the Royal Institution is handsomely endowed. On the contrary, it has often been in financial straits; and since its foundation by Count Rumford its only considerable bequests have been one from Thomas G. Hodgkins, an American citizen, for Experimental Research, and that of John Fuller for endowing with 95*l.* a year the chairs of Chemistry and Physiology. In this connection the Davy-Faraday Laboratory, founded by the liberality of Dr. Ludwig Mond, will naturally occur to many minds. But though affiliated to the Royal Institution, with, I hope, reciprocal indirect advantages, that Laboratory is financially independent and its endowments are devoted to its own special purpose, which is to provide opportunity to prosecute independent research for worthy and approved applicants of all nationalities. The main reliance of the Royal Institution has always been, and still remains, upon the contributions of its members, and upon corresponding sacrifices in the form of time and labour by its professors. It may be doubted whether we can reasonably count upon a succession of scientific men able and willing to make sacrifices which the conditions of modern life tend to render increasingly burdensome. Modern science is in fact in something of a dilemma. Devotion to abstract research upon small means is becoming always harder to maintain, while at the same time the number of wealthy independent searchers after truth and patrons of science of the style of Joule, Spottiswoode, and De la Rue is apparently becoming smaller. The installations required by the refinements of modern science are continually becoming more costly, so that upon all grounds it would appear that without endowments of the kind provided by Dr. Carnegie the outlook for disinterested research is rather dark. On the other hand, these endowments, unless carefully administered, might obviously tend to impair the single-minded devotion to the search after truth for its own sake to which science has owed almost every memorable advance made in the past. The Carnegie Institute will dispose in a year of as much money as the members of the Royal Institution have expended in a century upon its purely scientific work. It will at least be interesting to note how far the output of high-class scientific work corresponds to the hundredfold application of money to its production. Nor will it be of less interest to the people of this country to observe the results obtained from that moiety of Dr. Carnegie's gift to Scotland which is to be applied to the promotion of scientific research.

Applied Chemistry, English and Foreign.

The Diplomatic and Consular reports published from time to time by the Foreign Office are usually too belated to be of much use to business men, but they sometimes contain information concerning what is done in foreign countries which affords food for reflection. One of these reports, issued a year ago, gives a very good account of the German arrangements and provisions for scientific training, and of the enormous commercial demand for the services of men who have passed successfully through the universities and Technical High Schools, as well as of the wealth that has accrued to Germany through the systematic application of scientific proficiency to the ordinary business of life.

Taking these points in their order, I have thought it a matter of great interest to obtain a comparative view of chemical equipment in this country and in Germany, and I am indebted to Prof. Henderson of Glasgow, who last year became the secretary of a committee of this Association, of which Prof. Armstrong is chairman, for statistics referring to this country, which enable a comparison to be broadly made. The author of the Consular report estimates that in 1901 there were 4500 trained chemists employed in German works, the number having risen to this point from 1700 employed twenty-five years earlier. It is difficult to give perfectly accurate figures for this country, but a liberal estimate places the number of works chemists at 1500, while at the very outside it cannot be put higher than somewhere between 1500 and 2000. In other words, we cannot show in the United Kingdom, notwithstanding the immense range of the chemical industries in which we once stood prominent, more than one-third of the professional staff employed in Germany. It may perhaps be thought or hoped that we make up in quality for our defect in quantity, but unfortunately this is not the case. On the contrary, the German chemists are, on the average, as superior in technical training and acquirements as they are numerically. Details are given in the report of the training of 633 chemists employed in German works. Of these, 69 per cent. hold the degree of Ph.D., about 10 per cent. hold the diploma of a Technical High School, and about 5 per cent. hold both qualifications. That is to say, 84 per cent. have received a thoroughly systematic and complete chemical training, and 74 per cent. of these add the advantages of a university career. Compare with this the information furnished by 500 chemists in British works. Of these only 21 per cent. are graduates, while about 10 per cent. hold the diploma of a college. Putting the case as high as we can, and ignoring the more practical and thorough training of the German universities, which give their degrees for work done, and not for questions asked and answered on paper, we have only 31 per cent. of systematically trained chemists against 84 per cent. in German works. It ought to be mentioned that about 21 per cent. of the 500 are Fellows or Associates of the Institute of Chemistry, whatever that may amount to in practice, but of these a very large number have already been accounted for under the heads of graduates and holders of diplomas. These figures, which I suspect are much too favourable on the British side, unmistakably point to the prevalence among employers in this country of the antiquated adherence to rule of thumb, which is at the root of much of the backwardness we have to deplore. It hardly needs to be pointed out to such an audience as the present that chemists who are neither graduates of a university, nor holders of a diploma from a technical college, may be competent to carry on existing processes according to traditional methods, but are very unlikely to effect substantial improvements, or to invent new and more efficient processes. I am very far from denying that here and there an individual may be found whose exceptional ability enables him to triumph over all defects of training. But in all educational matters it is the average man whom we have to consider, and the average ability which we have to develop. Now, to take the second point—the actual money value of the industries carried on in Germany by an army of workers both quantitatively and qualitatively so superior to our own. The Consular report estimates the whole value of German chemical industries at not less than fifty millions sterling per annum. These industries have sprung up within the last seventy years, and have received enormous expansion during the last thirty. They are, moreover, very largely founded upon basic discoveries made by English chemists, but never properly appreciated or scientifically developed in the land of their birth. I will place before you some figures showing the growth of a single firm engaged in a single one of these industries—the utilisation of coal tar for the production of drugs, perfumes, and colouring-matters of every conceivable shade. The firm of Friedrich Bayer & Co. employed in 1875, 119 workmen. The number has more than doubled itself every five years, and in May of this year that firm employed 5000 workmen, 160 chemists, 260 engineers and mechanics, and 680 clerks. For many years past it has regularly paid 18 per cent. on the ordinary shares, which this year has risen to 20 per cent.; and in addition, in common

with other and even larger concerns in the same industry, has paid out of profits for immense extensions usually charged to capital account. There is one of these factories the works and plant of which stand in the books at 1,500,000*l.*, while the money actually sunk in them approaches to 5,000,000*l.* In other words, the practical monopoly enjoyed by the German manufacturers enables them to exact huge profits from the rest of the world, and to establish a position which, financially as well as scientifically, is almost unassailable. I must repeat that the fundamental discoveries upon which this gigantic industry is built were made in this country, and were practically developed to a certain extent by their authors. But in spite of the abundance and cheapness of the raw material, and in spite of the evidence that it could be most remuneratively worked up, these men founded no school and had practically no successors. The colours they made were driven out of the field by newer and better colours made from their stuff by the development of their ideas, but these improved colours were made in Germany and not in England. Now what is the explanation of this extraordinary and disastrous phenomenon? I give it in a word—want of education. We had the material in abundance when other nations had comparatively little. We had the capital, and we had the brains, for we originated the whole thing. But we did not possess the diffused education without which the ideas of men of genius cannot fructify beyond the limited scope of an individual. I am aware that our patent laws are sometimes held responsible. Well, they are a contributory cause; but it must be remembered that other nations with patent laws as protective as could be desired have not developed the colour industry. The patent laws have only contributed in a secondary degree, and if the patent laws have been bad, the reason for their badness is again want of education. Make them as bad as you choose, and you only prove that the men who made them, and the public whom these men try to please, were misled by theories instead of being conversant with fact and logic. But the root of the mischief is not in the patent laws or in any legislation whatever. It is in the want of education among our so-called educated classes, and secondarily among the workmen on whom these depend. It is in the abundance of men of ordinary plodding ability, thoroughly trained and methodically directed, that Germany at present has so commanding an advantage. It is the failure of our schools to turn out, and of our manufacturers to demand, men of this kind, which explains our loss of some valuable industries and our precarious hold upon others. Let no one imagine for a moment that this deficiency can be remedied by any amount of that technical training which is now the fashionable nostrum. It is an excellent thing, no doubt, but it must rest upon a foundation of general training. Mental habits are formed for good or evil long before men go to the technical schools. We have to begin at the beginning: we have to train the population from the first to think correctly and logically, to deal at first hand with facts, and to evolve, each one for himself, the solution of a problem put before him, instead of learning by rote the solution given by somebody else. There are plenty of chemists turned out, even by our Universities, who would be of no use to Bayer and Co. They are chock full of formulæ, they can recite theories, and they know text-books by heart; but put them to solve a new problem, freshly arisen in the laboratory, and you will find that their learning is all dead. It has not become a vital part of their mental equipment, and they are floored by the first emergence of the unexpected. The men who escape this mental barrenness are men who were somehow or other taught to think long before they went to the university. To my mind, the really appalling thing is not that the Germans have seized this or the other industry, or even that they may have seized upon a dozen industries. It is that the German population has reached a point of general training and specialised equipment which it will take us two generations of hard and intelligently directed educational work to attain. It is that Germany possesses a national weapon of precision which must give her an enormous initial advantage in any and every contest depending upon disciplined and methodised intellect.

History of Cold and the Absolute Zero.

It was Tyndall's good fortune to appear before you at a moment when a fruitful and comprehensive idea was vivifying the whole domain of scientific thought. At the present time no such broad generalisation presents itself for discussion, while on the other hand the number of specialised studies has enormously increased. Science is advancing in so broad a front by the efforts of so great an army of workers that it would be idle to attempt within the limits of an address to the most indulgent of audiences anything like a survey of chemistry alone. But I have thought it might be instructive, and perhaps not uninteresting, to trace briefly in broad outline the development of that branch of study with which my own labours have been recently more intimately connected—a study which I trust I am not too partial in thinking is as full of philosophical interest as of experimental difficulty. The nature of heat and cold must have engaged thinking men from the very earliest dawn of speculation upon the external world; but it will suffice for the present purpose if, disregarding ancient philosophers and even medieval alchemists, we take up the subject where it stood after the great revival of learning, and as it was regarded by the father of the inductive method. That this was an especially attractive subject to Bacon is evident from the frequency with which he recurs to it in his different works, always with lamentation over the inadequacy of the means at disposal for obtaining a considerable degree of cold. Thus in the chapter in the Natural History, "Sylva Sylvarum," entitled "Experiments in consort touching the production of cold," he says, "The production of cold is a thing very worthy of the inquisition both for the use and the disclosure of causes. For heat and cold are nature's two hands whereby she chiefly worketh, and heat we have in readiness in respect of the fire, but for cold we must stay till it cometh or seek it in deep caves or high mountains, and when all is done we cannot obtain it in any great degree, for furnaces of fire are far hotter than a summer sun, but vaults and hills are not much colder than a winter's frost." The great Robert Boyle was the first experimentalist who followed up Bacon's suggestions. In 1682 Boyle read a paper to the Royal Society on "New Experiments and Observations touching Cold, or an Experimental History of Cold," published two years later in a separate work. This is really a most complete history of everything known about cold up to that date, but its great merit is the inclusion of numerous experiments made by Boyle himself on frigorific mixtures, and the general effects of such upon matter. The agency chiefly used by Boyle in the conduct of his experiments was the glaciating mixture of snow or ice and salt. In the course of his experiments he made many important observations. Thus he observed that the salts which did not help the snow or ice to dissolve faster gave no effective freezing. He showed that water in becoming ice expands by about one-ninth of its volume, and bursts gun-barrels. He attempted to counteract the expansion and prevent freezing by completely filling a strong iron ball with water before cooling; anticipating that it might burst the bottle by the stupendous force of expansion, or that if it did not, then the ice produced might under the circumstances be heavier than water. He speculated in an ingenious way on the change of water into ice. Thus he says, "If cold be but a privation of heat through the recess of that ethereal substance which agitated the little eel-like particles of the water and thereby made them compose a fluid body, it may easily be conceived that they should remain rigid in the postures in which the ethereal substance quitted them, and thereby compose an unfluid body like ice; yet how these little eels should by that recess acquire as strong an endeavour outwards as if they were so many little springs and expand themselves with so stupendous a force, is that which does not so readily appear." The greatest degree of adventitious cold Boyle was able to produce did not make air exposed to its action lose a full tenth of its own volume, so that, in his own words, the cold does not "weaken the spring by anything near so considerable as one would expect." After making this remarkable observation and commenting upon its unexpected nature, it is strange Boyle did not follow it up. He questions the existence of a body of its own nature supremely cold, by participating in which all other bodies obtain that quality, although the doctrine of a *primum frigidum* had been accepted by many sects of philosophers; for, as he says, "if a body being cold signify no more than its not having its sensible parts so much agitated as those of our sensorium, it suffices that the sun or the fire or some other agent, whatever it were, that agitated more vehemently its parts before, does either now cease to agitate them or agitates them but very remissly, so that till it be determined whether cold be a positive quality or but a privative it will be needless to contend what particular body ought to be esteemed the *primum frigidum*." The whole elaborate investigation cost Boyle immense labour, and he confesses that he "never handled any part of natural

philosophy that was so troublesome and full of hardships." He looked upon his results but as a "beginning" in this field of inquiry, and for all the trouble and patience expended he consoled himself with the thought of "men being oftentimes obliged to suffer as much wet and cold and dive as deep to fetch up sponges as to fetch up pearls." After the masterly essay of Boyle, the attention of investigators was chiefly directed to improving thermometrical instruments. The old air thermometer of Galileo being inconvenient to use, the introduction of fluid thermometers greatly aided the inquiry into the action of heat and cold. For a time great difficulty was encountered in selecting proper fixed points on the scales of such instruments, and this stimulated men like Huygens, Newton, Hooke and Amontons to suggest remedies and to conduct experiments. By the beginning of the eighteenth century the freezing-point and the boiling-point of water were agreed upon as fixed points, and the only apparent difficulties to be overcome were the selection of the fluid, accurate calibration of the capillary tube of the thermometer, and a general understanding as to scale divisions. It must be confessed that great confusion and inaccuracy in temperature observations arose from the variety and crudeness of the instruments. This led Amontons in 1702–3 to contribute two papers to the French Academy which reveal great originality in the handling of the subject, and which, strange to say, are not generally known. The first discourse deals with some new properties of the air and the means of accurately ascertaining the temperature in any climate. He regarded heat as due to a movement of the particles of bodies, though he did not in any way specify the nature of the motion involved; and as the general cause of all terrestrial motion, so that in its absence the earth would be without movement in its smallest parts. The new facts he records are observations on the spring or pressure of air brought about by the action of heat. He shows that different masses of air measured at the same initial spring or pressure, when heated to the boiling-point of water, acquire equal increments of spring or pressure, provided the volume of the gas be kept at its initial value. Further, he proves that if the pressure of the gas before heating be doubled or tripled, then the additional spring or pressure resulting from heating to the boiling-point of water is equally doubled or tripled. In other words, the ratio of the total spring of air at two definite and steady temperatures and at constant volume is a constant, independent of the mass or the initial pressure of the air in the thermometer. These results led to the increased perfection of the air thermometer as a standard instrument, Amontons' idea being to express the temperature at any locality in fractions of the degree of heat of boiling water. The great novelty of the instrument is that temperature is defined by the measurement of the length of a column of mercury. In passing, he remarks that we do not know the extreme of heat and cold, but that he has given the results of experiments which establish correspondences for those who wish to consider the subject. In the following year Amontons contributed to the Academy a further paper extending the scope of the inquiry. He there pointed out more explicitly that as the degrees of heat in his thermometer are registered by the height of a column of mercury, which the heat is able to sustain by the spring of the air, it follows that the extreme cold of the thermometer will be that which reduces the air to have no power of spring. This, he says, will be a much greater cold than what we call "very cold," because experiments have shown that if the spring of the air at boiling-point is 73 inches, the degree of heat which remains in the air when brought to the freezing-point of water is still very great, for it can still maintain the spring of $51\frac{1}{2}$ inches. The greatest climatic cold on the scale of units adopted by Amontons is marked 50, and the greatest summer heat 58, the value for boiling water being 73, and the zero being 52 units below the freezing-point. Thus Amontons was the first to recognise that the use of air as a thermometric substance led to the inference of the existence of a zero of temperature, and his scale is nothing else than the absolute one we are now so familiar with. It results from Amontons' experiments that the air would have no spring left if it were cooled below the freezing-point of water to about $2\frac{1}{2}$ times the temperature range which separates the boiling-point and the freezing-point. In other words, if we adopt the usual centennial difference between these two points of temperature as 100 degrees, then the zero of Amontons' air thermometer is *minus* 240 degrees. This is a remarkable approximation to our modern value for the same point of *minus* 273 degrees. It has to be confessed that Amontons' valuable contributions to knowledge met with that fate which has so often for a time overtaken the work of too-advanced discoverers; in other words, it was simply ignored, or in any case not appreciated by the scientific world either of that time or half a century later. It is not till Lambert, in his work on "Pyrometrie" published in 1779, repeated Amontons' experiments and endorsed his results that we find any further reference to the absolute scale or the zero of temperature. Lambert's observations were made with the greatest care and refinement, and resulted in correcting the value of the zero of the air scale to *minus* 270 degrees as compared with Amontons' *minus* 240 degrees. Lambert points out that the degree of temperature which is equal to zero is what one may call absolute cold, and that at this temperature the volume of the air would be practically nothing. In other words, the particles of the air would fall together and touch each other and become dense like water; and from this it may be inferred that the gaseous condition is caused by heat. Lambert says that Amontons' discoveries had found few adherents because they were too beautiful and advanced for the time in which he lived.

About this time a remarkable observation was made by Prof. Braun at Moscow, who, during the severe winter of 1759, succeeded in freezing mercury by the use of a mixture of snow and nitric acid. When we remember that mercury was regarded as quite a peculiar substance possessed of the essential quality of fluidity, we can easily understand the universal interest created by the experiment of Braun. This was accentuated by the observations he made on the temperature given by the mercury thermometer, which appeared to record a temperature as low as *minus* 200° C. The experiments were soon repeated by Hutchins at Hudson's Bay, who conducted his work with the aid of suggestions given him by Cavendish and Black. The result of the new observations was to show that the freezing-point of mercury is only *minus* 40° C., the errors in former experiments having been due to the great contraction of the mercury in the thermometer in passing into the solid state. From this it followed that the enormous natural and artificial colds which had generally been believed in had no proved existence. Still the possible existence of a zero of temperature very different from that deduced from gas thermometry had the support of such distinguished names as those of Laplace and Lavoisier. In their great memoir on "Heat," after making what they consider reasonable hypotheses as to the relation between specific heat and total heat, they calculate values for the zero which range from 1500° to 3000° below melting ice. On the whole, they regard the absolute zero as being in any case 600° below the freezing-point. Lavoisier, in his "Elements of Chemistry" published in 1792, goes further in the direction of indefinitely lowering the zero of temperature when he says, "We are still very far from being able to produce the degree of absolute cold, or total deprivation of heat, being unacquainted with any degree of coldness which we cannot suppose capable of still further augmentation; hence it follows we are incapable of causing the ultimate particles of bodies to approach each other as near as possible, and thus these particles do not touch each other in any state hitherto known." Even as late as the beginning of the nineteenth century we find Dalton, in his new system of "Chemical Philosophy," giving ten calculations of this value, and adopting finally as the natural zero of temperature *minus* 3000° C.

In Black's lectures we find that he takes a very cautious view with regard to the zero of temperature, but as usual is admirably clear with regard to its exposition. Thus he says, "We are ignorant of the lowest possible degree or beginning of heat. Some ingenious attempts have been made to estimate what it may be, but they have not proved satisfactory. Our knowledge of the degrees of heat may be compared to what we should have of a chain the two ends of which were hidden from us and the middle only exposed to our view. We might put distinct marks on some of the links, and number the rest according as they are nearest to or further removed from the principal links; but not knowing the distance of any links from the end of the chain we could not compare them together with respect to their distance, or say that one link was twice as far from the end of the chain as another." It is interesting to observe, however, that Black was evidently well acquainted with the work of Amontons, and strongly supports his inference as to the nature of air. Thus, in discussing the general cause of vaporisation, Black says that some philoso-

phers have adopted the view "that every palpable elastic fluid in nature is produced and preserved in this form by the action of heat. Mr. Amontons, an ingenious member of the late Royal Academy of Sciences, at Paris, was the first who proposed this idea with respect to the atmosphere. He supposed that it might be deprived of the whole of its elasticity and condensed and even frozen into a solid matter were it in our power to apply to it a sufficient cold; that it is a substance that differs from others by being incomparably more volatile, and which is therefore converted into vapour and preserved in that form by a weaker heat than any that ever happened or can obtain in this globe, and which therefore cannot appear under any other form than the one it now wears, so long as the constitution of the world remains the same as at present." The views that Black attributes to Amontons have been generally associated with the name of Lavoisier, who practically admitted similar possibilities as to the nature of air; but it is not likely that in such matters Black would commit any mistake as to the real author of a particular idea, especially in his own department of knowledge. Black's own special contribution to low-temperature studies was his explanation of the interaction of mixtures of ice with salts and acids by applying the doctrine of the latent heat of fluidity of ice to account for the frigorific effect. In a similar way, Black explained the origin of the cold produced in Cullen's remarkable experiment of the evaporation of ether under the receiver of an air-pump by pointing out that the latent heat of vaporisation in this case necessitated such a result. Thus, by applying his own discoveries of latent heat, Black gave an intelligent explanation of the cause of all the low-temperature phenomena known in his day.

After the gaseous laws had been definitely formulated by Gay-Lussac and Dalton, the question of the absolute zero of temperature, as deduced from the properties of gases, was revived by Clement and Desormes. These distinguished investigators presented a paper on the subject to the French Academy in 1812, which, it appears, was rejected by that body. The authors subsequently elected to publish it in 1819. Relying on what we know now to have been a faulty hypothesis, they deduced from observations on the heating of air rushing into a vacuum the temperature of *minus* 267 degrees as that of the absolute zero. They further endeavoured to show, by extending to lower temperatures the volume or the pressure coefficients of gases given by Gay-Lussac, that at the same temperature of *minus* 267 degrees the gases would contract so as to possess no appreciable volume, or, alternatively, if the pressure was under consideration, it would become so small as to be non-existent. Although full reference is given to previous work bearing on the same subject, yet, curiously enough, no mention is made of the name of Amontons. It certainly gave remarkable support to Amontons' notion of the zero to find that simple gases like hydrogen and compound gases like ammonia, hydrochloric, carbonic and sulphurous acids should all point to substantially the same value for this temperature. But the most curious fact about this research of Clement and Desormes is that Gay-Lussac was a bitter opponent of the validity of the inferences they drew either from his work or their own. The mode in which Gay-Lussac regarded the subject may be succinctly put as follows: A quick compression of air to one-fifth volume raises its temperature to 300 degrees, and if this could be made much greater and instantaneous the temperature might rise to 1000 or 2000 degrees. Conversely, if air under five atmospheres were suddenly dilated, it would absorb as much heat as it had evolved during compression, and its temperature would be lowered by 300 degrees. Therefore, if air were taken and compressed to fifty atmospheres or more, the cold produced by its sudden expansion would have no limit. In order to meet this position, Clement and Desormes adopted the following reasoning: They pointed out that it had not been proved that Gay-Lussac was correct in his hypothesis, but that in any case it tacitly involves the assumption that a limited quantity of matter possesses an unlimited supply of heat. If this were the case, then heat would be unlike any other measurable thing or quality. It is, therefore, more consistent with the course of nature to suppose that the amount of heat in a body is like the quantity of elastic fluid filling a vessel, which, while definite in original amount, one may make less and less by getting nearer to a complete exhaustion. Further, to realise the absolute zero in the one case is just as impossible as to realise the absolute vacuum in the other; and as we do not doubt a zero of pressure, although it is unattainable, for the same reason we ought to accept the reality of the absolute zero. We know now that Gay-Lussac was wrong in supposing the increment of temperature arising from a given gaseous compression would produce a corresponding decrement from an identical expansion. After this time the zero of temperature was generally recognised as a fixed ideal point, but in order to show that it was hypothetical a distinction was drawn between the use of the expressions, zero of absolute temperature and the absolute zero.

The whole question took an entirely new form when Lord Kelvin, in 1848, after the mechanical equivalent of heat had been determined by Joule, drew attention to the great principles underlying Carnot's work on the "Motive Power of Heat," and applied them to an absolute method of temperature measurement, which is completely independent of the properties of any particular substance. The principle was that for a difference of one degree on this scale, between the temperatures of the source and refrigerator, a perfect engine should give the same amount of work in every part of the scale. Taking the same fixed points as for the Centigrade scale, and making 100 of the new degrees cover that range, it was found that the degrees not only within that range, but as far beyond as experimental data supplied the means of comparison, differed by only minute quantities from those of Regnault's air thermometer. The zero of the new scale had to be determined by the consideration that when the refrigerator was at the zero of temperature the perfect engine should give an amount of work equal to the full mechanical equivalent of the heat taken up. This led to a zero of 273 degrees below the temperature of freezing water, substantially the same as that deduced from a study of the gaseous state. It was a great advance to demonstrate by the application of the laws of thermodynamics not only that the zero of temperature is a reality, but that it must be located at 273 degrees below the freezing-point of water. As no one has attempted to impugn the solid foundation of theory and experiment on which Lord Kelvin based his thermodynamic scale, the existence of a definite zero of temperature must be acknowledged as a fundamental scientific fact.

Liquefaction of Gases and Continuity of State.

In these speculations, however, chemists were dealing theoretically with temperatures to which they could not make any but the most distant experimental approach. Cullen, the teacher of Black, had indeed shown how to lower temperature by the evaporation of volatile bodies, such as ether, by the aid of the air-pump, and the later experiments of Leslie and Wollaston extended the same principle. Davy and Faraday made the most of the means at command in liquefying the more condensable gases, while at the same time Davy pointed out that they in turn might be utilised to procure greater cold by their rapid reconversion into the aëriform state. Still the chemist was sorely hampered by the want of some powerful and accessible agent for the production of temperatures much lower than had ever been attained. That want was supplied by Thilorier, who in 1835 produced liquid carbonic acid in large quantities, and further made the fortunate discovery that the liquid could be frozen into a snow by its own evaporation. Faraday was prompt to take advantage of this new and potent agent. Under exhaustion he lowered its boiling-point from *minus* 78° C. to *minus* 110° C., and by combining this low temperature with pressure all the gases were liquefied by the year 1844, with the exception of the three elementary gases—hydrogen, nitrogen, and oxygen, and three compound gases—carbonic oxide, marsh gas, and nitric oxide; Andrews some twenty-five years after the work of Faraday attempted to induce change of state in the uncondensed gases by using much higher pressures than Faraday employed. Combining the temperature of a solid carbonic acid bath with pressures of 300 atmospheres, Andrews found that none of these gases exhibited any appearance of liquefaction in such high states of condensation; but so far as change of volume by high compression went, Andrews confirmed the earlier work of Natterer by showing that the gases become proportionately less compressible with growing pressure. While such investigations were proceeding, Regnault and Magnus had completed their refined investigations on the laws of Boyle and Gay-Lussac. A very important series of experiments was made by Joule and Kelvin "On the Thermal Effects of Fluids in Motion" about 1862, in which the thermometrical effects of passing gases under compression through porous plugs furnished important data for the study of the mutual action of the gas

molecules. No one, however, had attempted to make a complete study of a liquefiable gas throughout wide ranges of temperature. This was accomplished by Andrews in 1869, and his Bakerian Lecture "On the Continuity of the Gaseous and Liquid States of Matter" will always be regarded as an epoch-making investigation. During the course of this research Andrews observed that liquid carbonic acid raised to a temperature of 31° C. lost the sharp concave surface of demarcation between the liquid and the gas, the space being now occupied by a homogeneous fluid which exhibited, when the pressure was suddenly diminished or the temperature slightly lowered, a peculiar appearance of moving or flickering striæ, due to great local alterations of density. At temperatures above 31° C. the separation into two distinct kinds of matter could not be effected even when the pressure reached 400 atmospheres. This limiting temperature of the change of state from gas to liquid Andrews called the critical temperature. He showed that this temperature is constant, and differs with each substance, and that it is always associated with a definite pressure peculiar to each body. Thus the two constants, critical temperature and pressure, which have been of the greatest importance in subsequent investigations, came to be defined, and a complete experimental proof was given that "the gaseous and liquid states are only two distinct stages of the same condition of matter and are capable of passing into one another by a process of continuous change."

In 1873 an essay "On the Continuity of the Gaseous and Liquid State," full of new and suggestive ideas, was published by van der Waals, who, recognising the value of Clausius' new conception of the Virial in Dynamics, for a long-continued series of motions, either oscillatory or changing exceedingly slowly with time, applied it to the consideration of the molecular movements of the particles of the gaseous substance, and after much refined investigation, and the fullest experimental calculation available at the time, devised his well-known Equation of Continuity. Its paramount merit is that it is based entirely on a mechanical foundation, and is in no sense empiric; we may therefore look upon it as having a secure foundation in fact, but as being capable of extension and improvement. James Thomson, realising that the straight-line breach of continuous curvature in the Andrews isothermals was untenable to the physical mind, propounded his emendation of the Andrews curves—namely, that they were continuous and of S form. We also owe to James Thomson the conception and execution of a three-dimensional model of Andrews' results, which has been of the greatest service in exhibiting the three variables by means of a specific surface afterwards greatly extended and developed by Prof. Willard Gibbs. The suggestive work of James Thomson undoubtedly was a valuable aid to van der Waals, for as soon as he reached the point where his equation had to show the continuity of the two states this was the first difficulty he had to encounter, and he succeeded in giving the explanation. He also gave a satisfactory reason for the existence of a minimum value of the product of volume and pressure in the Regnault isothermals. His isothermals, with James Thomson's completion of them, were now shown to be the results of the laws of dynamics. Andrews applied the new equation to the consideration of the coefficients of expansion with temperature and of pressure with temperature, showing that although they were nearly equal, nevertheless they were almost independent quantities. His investigation of the capillarity constant was masterly, and he added further to our knowledge of the magnitudes of the molecules of gases and of their mean free paths. Following up the experiments of Joule and Kelvin, he showed how their cooling coefficients could be deduced, and proved that they vanished at a temperature in each case which is a constant multiple of the specific critical temperature. The equation of continuity developed by van der Waals involved the use of three constants instead of one, as in the old law of Boyle and Charles, the latter being only utilised to express the relation of temperature, pressure, and volume, when the gas is far removed from its point of liquefaction. Of the two new constants one represents the molecular pressure arising from the attraction between the molecules, the other four times the volume of the molecules. Given these constants of a gas, van der Waals showed that his equation not only fitted into the general characters of the isothermals, but also gave the values of the critical temperature, the critical pressure and the critical volume. In the case of carbonic acid the theoretical results were found to be in remarkable agreement with the experimental values of Andrews. This gave chemists the means of ascertaining the critical constants, provided sufficiently accurate data derived from the study of a few properly distributed isothermals of the gaseous substance were available. Such important data came into the possession of chemists when Amagat published his valuable paper on "The Isothermals of Hydrogen, Nitrogen, Oxygen, Ethylene, &c.," in the year 1880. It now became possible to calculate the critical data with comparative accuracy for the so-called permanent gases oxygen and nitrogen, and this was done by Sarrau in 1882. In the meantime a great impulse had been given to a further attack upon the so-called permanent gases by the suggestive experiments made by Pictet and Cailletet. The static liquefaction of oxygen was effected by Wroblewski in 1883, and thereby the theoretical conclusions derived from van der Waals' equation were substantially confirmed. The liquefaction of oxygen and air was achieved through the use of liquid ethylene as a cooling agent, which enabled a temperature of *minus* 140 degrees to be maintained by its steady evaporation *in vacuo*. From this time liquid oxygen and air came to be regarded as the potential cooling agents for future research, commanding as they did a temperature of 200 degrees below melting ice. The theoretical side of the question received at the hands of van der Waals a second contribution, which was even more important than his original essay, and that was his novel and ingenious development of what he calls "The Theory of Corresponding States." He defined the corresponding states of two substances as those in which the ratios of the temperature, pressure and volume to the critical temperature, pressure and volume respectively were the same for the two substances, and in corresponding states he showed that the three pairs of ratios all coincided. From this a series of remarkable propositions was developed, some new, some proving previous laws that were hitherto only empiric, and some completing and correcting faulty though approximate laws. As examples, he succeeded in calculating the boiling-point of carbonic acid from observations on ether vapour, proved Kopp's law of molecular volumes, and showed that at corresponding temperatures the molecular latent heats of vaporisation are proportional to the absolute critical temperature, and that under the same conditions the coefficients of liquid expansion are inversely proportional to the absolute critical temperature, and that the coefficients of liquid compressibility are inversely proportional to the critical pressure. All these propositions and deductions are in the main correct, though further experimental investigation has shown minor discrepancies requiring explanation. Various proposals have been made to supplement van der Waals' equation so as to bring it into line with experiments, some being entirely empiric, others theoretical. Clausius, Sarrau, Wroblewski, Batteli, and others attacked the question empirically, and in the main preserved the co-volume (depending on the total volume of the molecules) unaltered while trying to modify the constant of molecular attraction. Their success depended entirely on the fact that, instead of limiting the number of constants to three, some of them have increased them to as many as ten. On the other hand, a series of very remarkable theoretical investigations has been made by van der Waals himself, by Kammerlingh Onnes, Korteweg, Jaeger, Boltzmann, Dieterici, and Rienganum, and others, all directed in the main towards an admitted variation in the value of the co-volume while preserving the molecular attraction constant. The theoretical reductions of Tait lead to the conclusion that a substance below its critical point ought to have two different equations of the van der Waals type, one referring to the liquid and the other to the gaseous phase. One important fact was soon elicited—namely, that the law of correspondence demanded only that the equation should contain not more than three constants for each body. The simplest extension is that made by Reinganum, in which he increased the pressure for a given mean kinetic energy of the particles inversely in the ratio of the diminution of free volume, due to the molecules possessing linear extension. Berthelot has shown how a "reduced" isothermal may be got by taking two other prominent points as units of measurement instead of the critical coordinates. The most suggestive advance in the improvement of the van der Waals equation has been made by a lady, Mme. Christine Meyer. The idea at the base of this new development may be understood from the following general statement: van der Waals brings the van der Waals surfaces for all substances into coincidence at the point where volume, pressure and temperature are nothing, and then stretches or compresses all the surfaces parallel to the three axes of volume,

pressure and temperature until their critical points coincide. But on this plan the surfaces do not quite coincide, because the points where the three variables are respectively nothing are not corresponding points. Mme. Meyer's plan is to bring all the critical points first into coincidence, and then to compress or extend all the representative surfaces parallel to the three axes of volume, pressure and temperature until the surfaces coincide. In this way, taking twenty-nine different substances, she completely verifies from experiment van der Waals' law of correspondence. The theory of van der Waals has been one of the greatest importance in directing experimental investigation and in attacking the difficult problems of the liquefaction of the most permanent gases. One of its greatest triumphs has been the proof that the critical constants and the boiling-point of hydrogen theoretically deduced by Wroblewski from a study of the isothermals of the gas taken far above the temperature of liquefaction are remarkably near the experimental values. We may safely infer, therefore, that if hereafter a gas be discovered in small quantity even four times more volatile than liquid hydrogen, yet by a study of its isothermals at low temperature we shall succeed in finding its most important liquid constants, although the isolation of the real liquid may for the time be impossible. It is perhaps not too much to say that, as a prolific source of knowledge in the department dealing with the continuity of state in matter, it would be necessary to go back to Carnot's cycle to find a proposition of greater importance than the theory of van der Waals and his development of the law of corresponding states.

It will be apparent from what has just been said that, thanks to the labours of Andrews, van der Waals, and others, theory had again far outrun experiment. We could calculate the constants and predict some of the simple physical characteristics of liquid oxygen, hydrogen or nitrogen with a high degree of confidence long before any one of the three had been obtained in the static liquid condition permitting of the experimental verification of the theory. This was the more tantalising, because, with whatever confidence the chemist may anticipate the substantial corroboration of his theory, he also anticipates with almost equal conviction that, as he approaches more and more nearly to the zero of absolute temperature, he will encounter phenomena compelling modification, revision and refinement of formulas which fairly covered the facts previously known. Just as nearly seventy years ago chemists were waiting for some means of getting a temperature of 100 degrees below melting ice, so ten years ago they were casting about for the means of going 100 degrees lower still. The difficulty, it need hardly be said, increases in a geometrical rather than in an arithmetical ratio. Its magnitude may be estimated from the fact that to produce liquid air in the atmosphere of an ordinary laboratory is a feat analogous to the production of liquid water starting from steam at a white heat, and working with all the implements and surroundings at the same high temperature. The problem was not so much how to produce intense cold as how to save it when produced from being immediately levelled up by the relatively superheated surroundings. Ordinary non-conducting packings were inadmissible because they are both cumbrous and opaque, while in working near the limits of our resources it is essential that the product should be visible and readily handled. It was while puzzling over this mechanical and manipulative difficulty in 1892 that it occurred to me that the principle of an arrangement used nearly twenty years before in some calorimetric experiments, which was based upon the work of Dulong and Petit on radiation, might be employed with advantage as well to protect old substances from heat as hot ones from rapid cooling. I therefore tried the effect of keeping liquefied gases in vessels having a double wall, the annular space between being very highly exhausted. Experiments showed that liquid air evaporated at only one-fifth of the rate prevailing when it was placed in a similar unexhausted vessel, owing to the convective transference of heat by the gas particles being enormously reduced by the high vacuum. But, in addition, these vessels lend themselves to an arrangement by which radiant heat can also be cut off. It was found that when the inner walls were coated with a bright deposit of silver the influx of heat was diminished to one-sixth the amount entering without the metallic coating. The total effect of the high vacuum and the silvering is to reduce the ingoing heat to about 3 per cent. The efficiency of such vessels depends upon getting as high a vacuum as possible, and cold is one of the best means of effecting the desired exhaustion. All that is necessary is to fill completely the space that has to be exhausted with an easily condensable vapour, and then to freeze it out in a receptacle attached to the primary vessel that can be sealed off. The advantage of this method is that no air-pump is required, and that theoretically there is no limit to the degree of exhaustion that can be obtained. The action is rapid, provided liquid air is the cooling agent, and vapours like mercury, water or benzol are employed. It is obvious that when we have to deal with such an exceptionally volatile liquid as hydrogen, the vapour filling may be omitted because air itself is now an easily condensable vapour. In other words, liquid hydrogen, collected in such vessels with the annular space full of air, immediately solidifies the air and thereby surrounds itself with a high vacuum. In the same way, when it shall be possible to collect a liquid boiling on the absolute scale at about 5 degrees, as compared with the 20 degrees of hydrogen, then you might have the annular space filled with the latter gas to begin with, and yet get directly a very high vacuum, owing to the solidification of the hydrogen. Many combinations of vacuum vessels can be arranged, and the lower the temperature at which we have to operate the more useful they become. Vessels of this kind are now in general use, and in them liquid air has crossed the American continent. Of the various forms, that variety is of special importance which has a spiral tube joining the bottom part of the walls, so that any liquid gas may be drawn off from the interior of such a vessel. In the working of regenerative coils such a device becomes all-important, and such special vessels cannot be dispensed with for the liquefaction of hydrogen.

In the early experiments of Pictet and Cailletet, cooling was produced by the sudden expansion of the highly compressed gas preferably at a low temperature, the former using a jet that lasted for some time, the latter an instantaneous adiabatic expansion in a strong glass tube. Neither process was practicable as a mode of producing liquid gases, but both gave valuable indications of partial change into the liquid state by the production of a temporary mist. Linde, however, saw that the continuous use of a jet of highly compressed gas, combined with regenerative cooling, must lead to liquefaction on account of what is called the Kelvin-Joule effect; and he succeeded in making a machine, based on this principle, capable of producing liquid air for industrial purposes. These experimenters had proved that, owing to molecular attraction, compressed gases passing through a porous plug or small aperture were lowered in temperature by an amount depending on the difference of pressure, and inversely as the square of the absolute temperature. This means that for a steady difference of pressure the cooling is greater the lower the temperature. The only gas that did not show cooling under such conditions was hydrogen. Instead of being cooled it became actually hotter. The reason for this apparent anomaly in the Kelvin-Joule effect is that every gas has a thermometric point of inversion above which it is heated and below which it is cooled. This inversion point, according to van der Waals, is six and three-quarter times the critical point. The efficiency of the Linde process depend on working with highly compressed gas well below the inversion temperature, and in this respect this point may be said to take the place of the critical one, when in the ordinary way direct liquefaction is being effected by the use of specific liquid cooling agents. The success of both processes depends upon working within a certain temperature range, only the Linde method gives us a much wider range of temperature within which liquefaction can be effected. This is not the case if, instead of depending on getting cooling by the internal work done by the attraction of the gas molecules, we force the compressed gas to do external work as in the well-known air machines of Kirk and Coleman. Both these inventors have pointed out that there is no limit of temperature, short of liquefaction of the gas in use in the circuit, that such machines are not capable of giving. While it is theoretically clear that such machines ought to be capable of maintaining the lowest temperatures, and that with the least expenditure of power, it is a very different matter to overcome the practical difficulties of working such machines under the conditions. Coleman kept a machine delivering air at *minus* 83 degrees for hours, but he did not carry his experiments any further. Recently Monsieur Claude, of Paris, has, however, succeeded in working a machine of this type so efficiently that he has managed to produce one litre of liquid air per horse power expended per hour in the running of the engine. This output is twice as good as that given by the Linde machine,

and there is no reason to doubt that the yield will be still further improved. It is clear, therefore, that in the immediate future the production of liquid air and hydrogen will be effected most economically by the use of machines producing cold by the expenditure of mechanical work.

Liquid Hydrogen and Helium.

To the physicist the copious production of liquid air by the methods described was of peculiar interest and value as affording the means of attacking the far more difficult problem of the liquefaction of hydrogen, and even as encouraging the hope that liquid hydrogen might in time be employed for the liquefaction of yet more volatile elements, apart from the importance which its liquefaction must hold in the process of the steady advance towards the absolute zero. Hydrogen is an element of especial interest, because the study of its properties and chemical relations led great chemists like Faraday, Dumas, Daniel, Graham and Andrews to entertain the view that if it could ever be brought into the state of liquid or solid it would reveal metallic characters. Looking to the special chemical relations of the combined hydrogen in water, alkaline oxides, acids and salts, together with the behaviour of these substances on electrolysis, we are forced to conclude that hydrogen behaves as the analogue of a metal. After the beautiful discovery of Graham that palladium can absorb some hundreds of times its own volume of hydrogen and still retain its lustre and general metallic character, the impression that hydrogen was probably a member of the metallic group became very general. The only chemist who adopted another view was my distinguished predecessor, Prof. Odling. In his "Manual of Chemistry," published in 1861, he pointed out that hydrogen has chlorous as well as basic relations, and that they are as decided, important, and frequent as its other relations. From such considerations he arrived at the conclusion that hydrogen is essentially a neutral or intermediate body, and therefore we should not expect to find liquid or solid hydrogen possess the appearance of a metal. This extraordinary prevision, so characteristic of Odling, was proved to be correct some thirty-seven years after it was made. Another curious anticipation was made by Dumas in a letter addressed to Pictet, in which he says that the metal most analogous to hydrogen is magnesium and that probably both elements have the same atomic volume, so that the density of hydrogen, for this reason, would be about the value elicited by subsequent experiments. Later on, in 1872, when Newlands began to arrange the elements in periodic groups, he regarded hydrogen as the lowest member of the chlorine family; but Mendeléeff in his later classification placed hydrogen in the group of the alkaline metals; on the other hand, Dr. Johnstone Stoney classes hydrogen with the alkaline earth metals and magnesium. From this speculative divergency it is clear no definite conclusion could be reached regarding the physical properties of liquid or solid hydrogen, and the only way to arrive at the truth was to prosecute low-temperature research until success attended the efforts to produce its liquefaction. This result I definitely obtained in 1898. The case of liquid hydrogen is, in fact, an excellent illustration of the truth already referred to, that no theoretical forecast, however apparently justified by analogy, can be finally accepted as true until confirmed by actual experiment. Liquid hydrogen is a colourless, transparent body of extraordinary intrinsic interest. It has a clearly defined surface, is easily seen, drops well, in spite of the fact that its surface tension is only the thirty-fifth part of that of water, or about one-fifth that of liquid air, and can be poured easily from vessel to vessel. The liquid does not conduct electricity, and, if anything, is slightly diamagnetic. Compared with an equal volume of liquid air, it requires only one-fifth the quantity of heat for vaporisation; on the other hand, its specific heat is ten times that of liquid air or five times that of water. The coefficient of expansion of the fluid is remarkable, being about ten times that of gas; it is by far the lightest liquid known to exist, its density being only one-fourteenth that of water; the lightest liquid previously known was liquid marsh gas, which is six times heavier. The only solid which has so small density as to float upon its surface is a piece of pith wood. It is by far the coldest liquid known. At ordinary atmospheric pressure it boils at *minus* 252·5 degrees or 20·5 degrees absolute. The critical point of the liquid is about 29 degrees absolute and the critical pressure not more than fifteen atmospheres. The vapour of the hydrogen arising from the liquid has nearly the density of air—that is, it is fourteen times that of the gas at the ordinary temperature. Reduction of the pressure by an air-pump brings down the temperature to *minus* 258 degrees, when the liquid becomes a solid resembling frozen foam, and this by further exhaustion is cooled to *minus* 260 degrees, or 13 degrees absolute, which is the lowest steady temperature that has been reached. The solid may also be got in the form of a clear, transparent ice, melting at about 15 degrees absolute, under a pressure of 55 mm., possessing the unique density of one-eleventh that of water. Such cold involves the solidification of every gaseous substance but one that is at present definitely known to the chemist, and so liquid hydrogen introduces the investigator to a world of solid bodies. The contrast between this refrigerating substance and liquid air is most remarkable. On the removal of the loose plug of cotton-wool used to cover the mouth of the vacuum vessel in which it is stored, the action is followed by a miniature snowstorm of solid air, formed by the freezing of the atmosphere at the point where it comes into contact with the cold vapour rising from the liquid. This solid air falls into the vessel and accumulates as a white snow at the bottom of the liquid hydrogen. When the outside of an ordinary test-tube is cooled by immersion in the liquid, it is soon observed to fill up with solid air, and if the tube be now lifted out a double effect is visible, for liquid air is produced both in the inside and on the outside of the tube—in the one case by the melting of the solid, and in the other by condensation from the atmosphere. A tuft of cotton-wool soaked in the liquid and then held near the pole of a strong magnet is attracted, and it might be inferred therefrom that liquid hydrogen is a magnetic body. This, however, is not the case: the attraction is due neither to the cotton-wool nor to the hydrogen—which indeed evaporates almost as soon as the tuft is taken out of the liquid—but to the oxygen of the air, which is well known to be a magnetic body, frozen in the wool by the extreme cold.

The strong condensing powers of liquid hydrogen afford a simple means of producing vacua of very high tenuity. When one end of a sealed tube containing ordinary air is placed for a short time in the liquid, the contained air accumulates as a solid at the bottom, while the higher part is almost entirely deprived of particles of gas. So perfect is the vacuum thus formed, that the electric discharge can be made to pass only with the greatest difficulty. Another important application of liquid air, liquid hydrogen, &c., is as analytic agents. Thus, if a gaseous mixture be cooled by means of liquid oxygen, only those constituents will be left in the gaseous state which are less condensable than oxygen. Similarly, if this gaseous residue be in its turn cooled in liquid hydrogen, a still further separation will be effected, everything that is less volatile than hydrogen being condensed to a liquid or solid. By proceeding in this fashion it has been found possible to isolate helium from a mixture in which it is present to the extent of only one part in one thousand. By the evaporation of solid hydrogen under the air-pump we can reach within 13 or 14 degrees of the zero, but there or thereabouts our progress is barred. This gap of 13 degrees might seem at first sight insignificant in comparison with the hundreds that have already been conquered. But to win one degree low down the scale is quite a different matter from doing so at higher temperatures; in fact, to annihilate these few remaining degrees would be a far greater achievement than any so far accomplished in low-temperature research. For the difficulty is twofold, having to do partly with process and partly with material. The application of the methods used in the liquefaction of gases becomes continually harder and more troublesome as the working temperature is reduced; thus, to pass from liquid air to liquid hydrogen—a difference of 60 degrees—is, from a thermodynamic point of view, as difficult as to bridge the gap of 150 degrees that separates liquid chlorine and liquid air. By the use of a new liquid gas exceeding hydrogen in volatility to the same extent as hydrogen does nitrogen, the investigator might get to within five degrees of the zero; but even a second hypothetical substance, again exceeding the first one in volatility to an equal extent, would not suffice to bring him quite to the point of his ambition. That the zero will ever be reached by man is extremely improbable. A thermometer introduced into regions outside the uttermost confines of the earth's atmosphere might approach the absolute zero, provided that its parts were highly transparent to all kinds of radiation, otherwise it would be affected by the radiation of the sun, and would therefore become heated. But supposing all difficulties to be overcome,

and the experimenter to be able to reach within a few degrees of the zero, it is by no means certain that he would find the near approach of the death of matter sometimes pictured. Any forecast of the phenomena that would be seen must be based on the assumption that there is continuity between the processes studied at attainable temperatures and those which take place at still lower ones. Is such an assumption justified? It is true that many changes in the properties of substances have been found to vary steadily with the degree of cold to which they are exposed. But it would be rash to take for granted that the changes which have been traced in explored regions continue to the same extent and in the same direction in those which are as yet unexplored. Of such a breakdown low-temperature research has already yielded a direct proof at least in one case. A series of experiments with pure metals showed that their electrical resistance gradually decreases as they are cooled to lower and lower temperatures, in such ratio that it appeared probable that at the zero of absolute temperature they would have no resistance at all and would become perfect conductors of electricity. This was the inference that seemed justifiable by observations taken at depths of cold which can be obtained by means of liquid air and less powerful refrigerants. But with the advent of the more powerful refrigerant liquid hydrogen it became necessary to revise that conclusion. A discrepancy was first observed when a platinum resistance thermometer was used to ascertain the temperature of that liquid boiling under atmospheric and reduced pressure. All known liquids, when forced to evaporate quickly by being placed in the exhausted receiver of an air-pump, undergo a reduction in temperature, but when hydrogen was treated in this way it appeared to be an exception. The resistance thermometer showed no reduction as was expected, and it became a question whether it was the hydrogen or the thermometer that was behaving abnormally. Ultimately, by the adoption of other thermometrical appliances, the temperature of the hydrogen was proved to be lowered by exhaustion as theory indicated. Hence it was the platinum thermometer which had broken down; in other words, the electrical resistance of the metal employed in its construction was not, at temperatures about *minus* 250° C., decreased by cold in the same proportion as at temperatures about *minus* 200°. This being the case, there is no longer any reason to suppose that at the absolute zero platinum would become a perfect conductor of electricity; and in view of the similarity between the behaviour of platinum and that of other pure metals in respect of temperature and conductivity, the presumption is that the same is true of them also. At any rate, the knowledge that in the case of at least one property of matter we have succeeded in attaining a depth of cold sufficient to bring about unexpected change in the law expressing the variation of that property with temperature, is sufficient to show the necessity for extreme caution in extending our inferences regarding the properties of matter near the zero of temperature. Lord Kelvin evidently anticipates the possibility of more remarkable electrical properties being met with in the metals near the zero. A theoretical investigation on the relation of "electrons" and atoms has led him to suggest a hypothetical metal having the following remarkable properties: below 1 degree absolute it is a perfect insulator of electricity, at 2 degrees it shows noticeable conductivity, and at 6 degrees it possesses high conductivity. It may safely be predicted that liquid hydrogen will be the means by which many obscure problems of physics and chemistry will ultimately be solved, so that the liquefaction of the last of the old permanent gases is as pregnant now with future consequences of great scientific moment as was the liquefaction of chlorine in the early years of the last century.

The next step towards the absolute zero is to find another gas more volatile than hydrogen, and that we possess in the gas occurring in cleveite, identified by Ramsay as helium, a gas which is widely distributed, like hydrogen, in the sun, stars and nebulæ. A specimen of this gas was subjected by Olszewski to liquid air temperatures, combined with compression and subsequent expansion, following the Cailletet method, and resulted in his being unable to discover any appearance of liquefaction, even in the form of mist. His experiments led him to infer that the boiling-point of the substance is probably below 9 degrees absolute. After Lord Rayleigh had found a new source of helium in the gases which are derived from the Bath springs, and liquid hydrogen became available as a cooling agent, a specimen of helium cooled in liquid hydrogen showed the formation of fluid, but this turned out to be owing to the presence of an unknown admixture of other gases. As a matter of fact, a year before the date of this experiment I had recorded indications of the presence of unknown gases in the spectrum of helium derived from this source. When subsequently such condensable constituents were removed, the purified helium showed no signs of liquefaction, even when compressed to 80 atmospheres, while the tube containing it was surrounded with solid hydrogen. Further, on suddenly expanding, no instantaneous mist appeared. Thus helium was definitely proved to be a much more volatile substance than hydrogen in either the liquid or solid condition. The inference to be drawn from the adiabatic expansion effected under the circumstances is that helium must have touched a temperature of from 9 to 10 degrees for a short time without showing any signs of liquefaction, and consequently that the critical point must be still lower. This would force us to anticipate that the boiling-point of the liquid will be about 5 degrees absolute, or liquid helium will be four times more volatile than liquid hydrogen, just as liquid hydrogen is four times more volatile than liquid air. Although the liquefaction of the gas is a problem for the future, this does not prevent us from safely anticipating some of the properties of the fluid body. It would be twice as dense as liquid hydrogen, with a critical pressure of only 4 or 5 atmospheres. The liquid would possess a very feeble surface-tension, and its compressibility and expansibility would be about four times that of liquid hydrogen, while the heat required to vaporise the molecule would be about one-fourth that of liquid hydrogen. Heating the liquid 1 degree above its boiling-point would raise the pressure by $1\frac{3}{4}$ atmospheres, which is more than four times the increment for liquid hydrogen. The liquid would be only seventeen times denser than its vapour, whereas liquid hydrogen is sixty-five times denser than the gas it gives off. Only some 3 or 4 degrees would separate the critical temperature from the boiling-point and the melting-point, whereas in liquid hydrogen the separation is respectively 10 and 15 degrees. As the liquid refractivities for oxygen, nitrogen and hydrogen are closely proportional to the gaseous values, and as Lord Rayleigh has shown that helium has only one-fourth the refractivity of hydrogen, although it is twice as dense, we must infer that the refractivity of liquid helium would also be about one-fourth that of liquid hydrogen. Now hydrogen has the smallest refractivity of any known liquid, and yet liquid helium will have only about one-fourth of this value—comparable, in fact, with liquid hydrogen just below its critical point. This means that the liquid will be quite exceptional in its optical properties, and very difficult to see. This may be the explanation of why no mist has been seen on its adiabatic expansion from the lowest temperatures. Taking all these remarkable properties of the liquid into consideration, one is afraid to predict that we are at present able to cope with the difficulties involved in its production and collection. Provided the critical point is, however, not below 8 degrees absolute, then from the knowledge of the conditions that are successful in producing a change of state in hydrogen through the use of liquid air, we may safely predict that helium can be liquefied by following similar methods. If, however, the critical point is as low as 6 degrees absolute, then it would be almost hopeless to anticipate success by adopting the process that works so well with hydrogen. The present anticipation is that the gas will succumb after being subjected to this process, only, instead of liquid air under exhaustion being used as the primary cooling agent, liquid hydrogen evaporating under similar circumstances must be employed. In this case, the resulting liquid would require to be collected in a vacuum vessel the outer walls of which are immersed in liquid hydrogen. The practical difficulties and the cost of the operation will be very great; but, on the other hand, the descent to a temperature within 5 degrees of the zero would open out new vistas of scientific inquiry, which would add immensely to our knowledge of the properties of matter. To command in our laboratories a temperature which would be equivalent to that which a comet might reach at an infinite distance from the sun would indeed be a great triumph for science. If the present Royal Institution attack on helium should fail, then we must ultimately succeed by adopting a process based on the mechanical production of cold through the performance of external work. When a turbine can be worked by compressed helium, the whole of the mechanism and circuits being kept surrounded with liquid hydrogen, then we need hardly doubt that the liquefaction will be effected. In

all probability gases other than helium will be discovered of greater volatility than hydrogen. It was at the British Association Meeting in 1896 that I made the first suggestion of the probable existence of an unknown element which would be found to fill up the gap between argon and helium, and this anticipation was soon taken up by others and ultimately confirmed. Later, in the Bakerian Lecture for 1901, I was led to infer that another member of the helium group might exist having the atomic weight about 2, and this would give us a gas still more volatile, with which the absolute zero might be still more nearly approached. It is to be hoped that some such element or elements may yet be isolated and identified as coronium or nebulium. If amongst the unknown gases possessing a very low critical point some have a high critical pressure instead of a low one, which ordinary experience would lead us to anticipate, then such difficultly liquefiable gases would produce fluids having different physical properties from any of those with which we are acquainted. Again, gases may exist having smaller atomic weights and densities than hydrogen, yet all such gases must, according to our present views of the gaseous state, be capable of liquefaction before the zero of temperature is reached. The chemists of the future will find ample scope for investigation within the apparently limited range of temperature which separates solid hydrogen from the zero. Indeed, great as is the sentimental interest attached to the liquefaction of these refractory gases, the importance of the achievement lies rather in the fact that it opens out new fields of research and enormously widens the horizon of physical science, enabling the natural philosopher to study the properties and behaviour of matter under entirely novel conditions. This department of inquiry is as yet only in its infancy, but speedy and extensive developments may be looked for, since within recent years several special cryogenic laboratories have been established for the prosecution of such researches, and a liquid-air plant is becoming a common adjunct to the equipment of the ordinary laboratory.

The Upper Air and Auroras.

The present liquid ocean, neglecting everything for the moment but the water, was at a previous period of the earth's history part of the atmosphere, and its condensation has been brought about by the gradual cooling of the earth's surface. This resulting ocean is subjected to the pressure of the remaining uncondensed gases, and as these are slightly soluble they dissolve to some extent in the fluid. The gases in solution can be taken out by distillation or by exhausting the water, and if we compare their volume with the volume of water as steam, we should find about 1 volume of air in 60,000 volumes of steam. This would then be about the rough proportion of the relatively permanent gas to condensable gas which existed in the case of the vaporised ocean. Now let us assume the surface of the earth gradually cooled to some 200 degrees below the freezing-point; then, after all the present ocean was frozen, and the climate became three times more intense than any Arctic frost, a new ocean of liquid air would appear, covering the entire surface of the frozen globe about thirty-five feet deep. We may now apply the same reasoning to the liquid air ocean that we formerly did to the water one, and this would lead us to anticipate that it might contain in solution some gases that may be far less condensable than the chief constituents of the fluid. In order to separate them we must imitate the method of taking the gases out of water. Assume a sample of liquid air cooled to the low temperature that can be reached by its own evaporation, connected by a pipe to a condenser cooled in liquid hydrogen; then any volatile gases present in solution will distil over with the first portions of the air, and can be pumped off, being uncondensable at the temperature of the condenser. In this way, a gas mixture, containing, of the known gases, free hydrogen, helium and neon, has been separated from liquid air. It is interesting to note in passing that the relative volatilities of water and oxygen are in the same ratio as those of liquid air and hydrogen, so that the analogy between the ocean of water and that of liquid air has another suggestive parallel. The total uncondensable gas separated in this way amounts to about one fifty-thousandth of the volume of the air, which is about the same proportion as the air dissolved in water. That free hydrogen exists in air in small amount is conclusively proved, but the actual proportion found by the process is very much smaller than Gautier has estimated by the combustion method. The recent experiments of Lord Rayleigh show that Gautier, who estimated the hydrogen present as one five-thousandth, has in some way produced more hydrogen than he can manage to extract from pure air by a repetition of the same process. The spectroscopic examination of these gases throws new light upon the question of the aurora and the nature of the upper air. On passing electric discharges through the tubes containing the most volatile of the atmospheric gases, they glow with a bright orange light, which is especially marked at the negative pole. The spectroscope shows that this light consists, in the visible part of the spectrum, chiefly of a succession of strong rays in the red, orange and yellow, attributed to hydrogen, helium and neon. Besides these, a vast number of rays, generally less brilliant, are distributed through the whole length of the visible spectrum. The greater part of these rays are of, as yet, unknown origin. The violet and ultra-violet part of the spectrum rivals in strength that of the red and yellow rays. As these gases probably include some of the gases that pervade interplanetary space, search was made for the prominent nebular, coronal and auroral lines. No definite lines agreeing with the nebular spectrum could be found, but many lines occurred closely coincident with the coronal and auroral spectrum. But before discussing the spectroscopic problem it will be necessary to consider the nature and condition of the upper air.

According to the old law of Dalton, supported by the modern dynamical theory of gases, each constituent of the atmosphere while acted upon by the force of gravity forms a separate atmosphere, completely independent, except as to temperature, of the others, and the relations between the common temperature and the pressure and altitude for each specific atmosphere can be definitely expressed. If we assume the altitude and temperature known, then the pressure can be ascertained for the same height in the case of each of the gaseous constituents, and in this way the percentage composition of the atmosphere at that place may be deduced. Suppose we start with a surface atmosphere having the composition of our air, only containing two ten-thousandths of hydrogen, then at thirty-seven miles, if a sample could be procured for analysis, we believe that it would be found to contain 12 per cent. of hydrogen and only 10 per cent. of oxygen. The carbonic acid practically disappears; and by the time we reach forty-seven miles, where the temperature is *minus* 132 degrees, assuming a gradient of 3·2 degrees per mile, the nitrogen and oxygen have so thinned out that the only constituent of the upper air which is left is hydrogen. If the gradient of temperature were doubled, the elimination of the nitrogen and oxygen would take place by the time thirty-seven miles was reached, with a temperature of *minus* 220 degrees. The permanence of the composition of the air at the highest altitudes, as deduced from the basis of the dynamical theory of gases, has been discussed by Stoney, Bryan, and others. It would appear that there is a consensus of opinion that the rate at which gases like hydrogen and helium could escape from the earth's atmosphere would be excessively slow. Considering that to compensate any such loss the same gases are being supplied by actions taking place in the crust of the earth, we may safely regard them as necessarily permanent constituents of the upper air. The temperature at the elevations we have been discussing would not be sufficient to cause any liquefaction of the nitrogen and oxygen, the pressure being so low. If we assume the mean temperature as about the boiling-point of oxygen at atmospheric pressure, then a considerable amount of the carbonic acid must solidify as a mist, if the air from a lower level be cooled to this temperature; and the same result might take place with other gases of relatively small volatility which occur in air. This would explain the clouds that have been seen at an elevation of fifty miles, without assuming the possibility of water vapour being carried up so high. The temperature of the upper air must be above that on the vapour pressure curve corresponding to the barometric pressure at the locality, otherwise liquid condensation must take place. In other words, the temperature must be above the dew-point of air at that place. At higher elevations, on any reasonable assumption of temperature distribution, we inevitably reach a temperature where the air would condense, just as Fourier and Poisson supposed it would, unless the temperature is arrested in some way from approaching the zero. Both ultra-violet absorption and the prevalence of electric storms may have something to do with the maintenance of a higher mean temperature. The whole mass of the air above forty miles is not more than one seven-hundredth part of the total mass of the atmosphere, so that any rain or snow of liquid

of solid air, if it did occur, would necessarily be of a very tenuous description. In any case, the dense gases tend to accumulate in the lower strata, and the lighter ones to predominate at the higher altitudes, always assuming that a steady state of equilibrium has been reached. It must be observed, however, that a sample of air taken at an elevation of nine miles has shown no difference in composition from that at the ground, whereas, according to our hypothesis, the oxygen ought to have been diminished to 17 per cent., and the carbonic acid should also have become much less. This can only be explained by assuming that a large intermixture of different layers of the atmosphere is still taking place at this elevation. This is confirmed by a study of the motions of clouds about six miles high, which reveals an average velocity of the air currents of some seventy miles an hour; such violent winds must be the means of causing the intermingling of different atmospheric strata. Some clouds, however, during hot and thundery weather, have been seen to reach an elevation of seventeen miles, so that we have direct proof that on occasion the lower layers of atmosphere are carried to a great elevation. The existence of an atmosphere at more than a hundred miles above the surface of the earth is revealed to us by the appearance of meteors and fireballs, and when we can take photographs of the spectrum of such apparitions we shall learn a great deal about the composition of the upper air. In the meantime Pickering's solitary spectrum of a meteor reveals an atmosphere of hydrogen and helium, and so far this is corroborative of the doctrine we have been discussing. It has long been recognised that the aurora is the result of electric discharges within the limits of the earth's atmosphere, but it was difficult to understand why its spectrum should be so entirely different from anything which could be produced artificially by electric discharges through rarefied air at the surface of the earth. Writing in 1879, Rand Capron, after collecting all the recorded observations, was able to enumerate no more than nine auroral rays, of which but one could with any probability be identified with rays emitted by atmospheric air under an electric discharge. Vogel attributed this want of agreement between nature and experiment, in a vague way, to difference of temperature and pressure; and Zollner thought the auroral spectrum to be one of a different order, in the sense in which the line and band spectra of nitrogen are said to be of different orders. Such statements were merely confessions of ignorance. But since that time observations of the spectra of auroras have been greatly multiplied, chiefly through the Swedish and Danish Polar Expeditions, and the length of spectrum recorded on the ultra-violet side has been greatly extended by the use of photography, so that, in a recent discussion of the results, M. Henri Stassano is able to enumerate upwards of one hundred auroral rays, of which the wave-length is more or less approximately known, some of them far in the ultra-violet. Of this large number of rays he is able to identify, within the probable limits of errors of observation, about two-thirds as rays, which Prof. Liveing and myself have observed to be emitted by the most volatile gases of atmospheric air unliquefiable at the temperature of liquid hydrogen. Most of the remainder he ascribes to argon, and some he might, with more probability, have identified with krypton or xenon rays, if he had been aware of the publication of wave-lengths of the spectra of those gases, and the identification of one of the highest rays of krypton with that most characteristic of auroras. The rosy tint often seen in auroras, particularly in the streamers, appears to be due mainly to neon, of which the spectrum is remarkably rich in red and orange rays. One or two neon rays are amongst those most frequently observed, while the red ray of hydrogen and one red ray of krypton have been noticed only once. The predominance of neon is not surprising, seeing that from its relatively greater proportion in air and its low density it must tend to concentrate at higher elevations. So large a number of probable identifications warrants the belief that we may yet be able to reproduce in our laboratories the auroral spectrum in its entirety. It is true that we have still to account for the appearance of some, and the absence of other, rays of the newly discovered gases, which in the way in which we stimulate them appear to be equally brilliant, and for the absence, with one doubtful exception, of all the rays of nitrogen. If we cannot give the reason of this, it is because we do not know the mechanism of luminescence—nor even whether the particles which carry the electricity are themselves luminous, or whether they only produce stresses causing other particles which encounter them to vibrate; yet we are certain that an electric discharge in a highly rarefied mixture of gases lights one element and not another, in a way which, to our ignorance, seems capricious. The Swedish North Polar Expedition concluded from a great number of trigonometrical measurements that the average above the ground of the base of the aurora was fifty kilometres (thirty-four miles) at Cape Thorsden, Spitzbergen; at this height the pressure of the nitrogen of the atmosphere would be only about one-tenth of a millimetre, and Moissan and Deslandres have found that in atmospheric air at pressures less than one millimetre the rays of nitrogen and oxygen fade and are replaced by those of argon and by five new rays which Stassano identifies with rays of the more volatile gases measured by us. Also Collie and Ramsay's observations on the distance to which electrical discharges of equal potential traverse different gases explosively throw much light on the question; for they find that, while for helium and neon this distance is from 250 to 300 mm., for argon it is $45\frac{1}{2}$ mm., for hydrogen it is 39 mm., and for air and oxygen still less. This indicates that a good deal depends on the very constitution of the gases themselves, and certainly helps us to understand why neon and argon, which exist in the atmosphere in larger proportions than helium, krypton or xenon, should make their appearance in the spectrum of auroras almost to the exclusion of nitrogen and oxygen. How much depends, not only on the constitution and it may be temperature of the gases, but also on the character of the electric discharge, is evident from the difference between the spectra at the cathode and anode in different gases, notably in nitrogen and argon, and not less remarkably in the more volatile compounds of the atmosphere. Paulsen thinks the auroral spectrum wholly due to cathodic rays. Without stopping to discuss that question, it is certain that changes in the character of the electric discharge produce definite changes in the spectra excited by them. It has long been known that in many spectra the rays which are inconspicuous with an uncondensed electric discharge become very pronounced when a Leyden jar is in the circuit. This used to be ascribed to a higher temperature in this condensed spark, though measurements of that temperature have not borne out the explanation. Schuster and Hemsalech have shown that these changes of spectra are in part due to the oscillatory character of the condenser discharge which may be enhanced by self-induction, and the corresponding change of spectrum thereby made more pronounced. Lightning we should expect to resemble condensed discharge much more than aurora, but this is not borne out by the spectrum. Pickering's recent analysis of the spectrum of a flash obtained by photography shows, out of nineteen lines measured by him, only two which can be assigned with probability to nitrogen and oxygen, while three hydrogen rays most likely due to water are very conspicuous, and eleven may be reasonably ascribed to argon, krypton and xenon, one to more volatile gas of the neon class, and the brightest ray of all is but a very little less refrangible than the characteristic auroral ray, and coincides with a strong ray of calcium, but also lies between, and close to, an argon and a neon ray, neither of them weak rays. There may be some doubt about the identification of the spectral rays of auroras because of the wide limits of the probable errors in measuring wave-lengths so faint as most of them are, but there is no such doubt about the wave-lengths of the rays in solar protuberances measured by Deslandres and Hale. Stassano found that these rays, forty-four in number, lying between the Fraunhofer line F and 3148 in the ultra-violet, agree very closely with rays which Prof. Liveing and myself measured in the spectra of the most volatile atmospheric gases. It will be remembered that one of the earliest suggestions as to the nature of solar prominences was that they were solar auroras. This supposition helped to explain the marvellous rapidity of their changes, and the apparent suspension of brilliant self-luminous clouds at enormous heights above the sun's surface. Now the identification of the rays of their spectra with those of the most volatile gases, which also furnish many of the auroral rays, certainly supports that suggestion. A stronger support, however, seems to be given to it by the results obtained at the total eclipse of May, 1901, by the American expedition to Sumatra. In the *Astrophysical Journal* for June last is a list of 339 lines in the spectrum of the corona photographed by Humphreys, during totality, with a very large concave grating. Of these no fewer than 209 do not differ from lines we have measured in the most volatile gases of the atmo-

sphere, or in krypton or xenon, by more than one unit of wave-length on Ångström's scale, a quantity within the limit of probable error. Of the remainder, a good many agree to a like degree with argon lines, a very few with oxygen lines and still fewer with nitrogen lines; the characteristic green auroral ray, which is not in the range of Humphreys' photographs, also agrees within a small fraction of a unit of wave-length with one of the rays emitted by the most volatile atmospheric gas. Taking into account the Fraunhofer lines H, K and G, usually ascribed to calcium, there remain only fifty-five lines of the 339 unaccounted for to the degree of probability indicated. Of these considerably more than half are very weak lines which have not depicted themselves on more than one of the six films exposed, and extend but a very short distance into the sun's atmosphere. There are, however, seven which are stronger lines, and reach to a considerable height above the sun's rim, and all have depicted themselves on at least four of the six films. If there be no considerable error in the wave-lengths assigned (and such is not likely to be the case), these lines may perhaps be due to some volatile element which may yet be discovered in our atmosphere. However that may be, the very great number of close coincidences between the auroral rays and those which are emitted under electric excitement by gases of our atmosphere almost constrains us to believe, what is indeed most probable on other grounds, that the sun's coronal atmosphere is composed of the same substances as the earth's, and that it is rendered luminous in the same way—namely, by electric discharges. This conclusion has plainly an important bearing on the explanation which should be given of the outburst of new stars and of the extraordinary and rapid changes in their spectra. Moreover, leaving on one side the question whether gases ever become luminous by the direct action of heat, apart from such transfers of energy as occur in chemical change and electric disturbance, it demands a revision of the theories which attribute more permanent differences between the spectra of different stars to differences of temperature, and a fuller consideration of the question whether they cannot with better reason be explained by differences in the electric conditions which prevail in the stellar atmosphere.

If we turn to the question what is the cause of the electric discharges which are generally believed to occasion auroras, but of which little more has hitherto been known than that they are connected with sun-spots and solar eruptions, recent studies of electric discharges in high vacua, with which the names of Crookes, Röntgen, Lenard, and J. J. Thomson will always be associated, have opened the way for Arrhenius to suggest a definite and rational answer. He points out that the frequent disturbances which we know to occur in the sun must cause electric discharges in the sun's atmosphere far exceeding any that occur in that of the earth. These will be attended with an ionisation of the gases, and the negative ions will stream away through the outer atmosphere of the sun into the interplanetary space, becoming, as Wilson has shown, nuclei of aggregation of condensable vapours and cosmic dust. The liquid and solid particles thus formed will be of various sizes: the larger will gravitate back to the sun, while those with diameters less than one and a half thousandths of a millimetre, but nevertheless greater than a wave-length of light, will, in accordance with Clerk-Maxwell's electromagnetic theory, be driven away from the sun by the incidence of the solar rays upon them, with velocities which may become enormous, until they meet other celestial bodies, or increase their dimensions by picking up more cosmic dust or diminish them by evaporation. The earth will catch its share of such particles on the side which is turned towards the sun, and its upper atmosphere will thereby become negatively electrified until the potential of the charge reaches such a point that a discharge occurs, which will be repeated as more charged particles reach the earth. This theory not only accounts for the auroral discharges, and the coincidence of their times of greatest frequency with those of the maxima of sunspots, but also for the minor maxima and minima. The vernal and autumnal maxima occur when the line through the earth and sun has its greatest inclination to the solar equator, so that the earth is more directly exposed to the region of maximum of sunspots, while the twenty-six days period corresponds closely with the period of rotation of that part of the solar surface where faculæ are most abundant. J. J. Thomson has pointed out, as a consequence of the Richardson observations, that negative ions will be constantly streaming from the sun merely regarded as a hot body, but this is not inconsistent with the supposition that there will be an excess of this emission in eruptions, and from the regions of faculæ. Arrhenius' theory accounts also, in a way which seems the most satisfactory hitherto enunciated, for the appearances presented by comets. The solid parts of these objects absorb the sun's rays, and as they approach the sun become heated on the side turned towards him until the volatile substances frozen in or upon them are evaporated and diffused in the gaseous state in surrounding space, where they get cooled to the temperature of liquefaction and aggregated in drops about the negative ions. The larger of these drops gravitate towards the sun and form clouds of the coma about the head, while the smaller are driven by the incidence of the sun's light upon them away from the sun and form the tail. The curvature of the tail depends, as Bredichin has shown, on the rate at which the particles are driven, which in turn depends on the size and specific gravity of the particles, and these will vary with the density of the vapour from which they are formed and the frequency of the negative ions which collect them. In any case Arrhenius' theory is a most suggestive one, not only with reference to auroras and comets, and the solar corona and chromosphere, but also as to the constitution of the photosphere itself.

Various Low-Temperature Researches.

We may now summarise some of the results which have already been attained by low-temperature studies. In the first place, the great majority of chemical interactions are entirely suspended, but an element of such exceptional powers of combination as fluorine is still active at the temperature of liquid air. Whether solid fluorine and liquid hydrogen would interact no one can at present say. Bodies naturally become denser, but even a highly expansive substance like ice does not appear to reach the density of water at the lowest temperature. This is confirmatory of the view that the particles of matter under such conditions are not packed in the closest possible way. The force of cohesion is greatly increased at low temperatures, as is shown by the additional stress required to rupture metallic wires. This fact is of interest in connection with two conflicting theories of matter. Lord Kelvin's view is that the forces that hold together the particles of bodies may be accounted for without assuming any other agency than gravitation or any other law than the Newtonian. An opposite view is that the phenomena of the aggregation of molecules depend upon the molecular vibration as a physical cause. Hence, at the zero of absolute temperature, this vibrating energy being in complete abeyance, the phenomena of cohesion should cease to exist, and matter generally be reduced to an incoherent heap of cosmic dust. This second view receives no support from experiment.

The photographic action of light is diminished at the temperature of liquid air to about 20 per cent. of its ordinary efficiency, and at the still lower temperature of liquid hydrogen only about 10 per cent. of the original sensitivity remains. At the temperature of liquid air or liquid hydrogen a large range of organic bodies and many inorganic ones acquire under exposure to violet light the property of phosphorescence. Such bodies glow faintly so long as they are kept cold, but become exceedingly brilliant during the period when the temperature is rising. Even solid air is a phosphorescent body. All the alkaline earth sulphides which phosphoresce brilliantly at the ordinary temperature lose this property when cooled, to be revived on heating; but such bodies in the first instance may be stimulated through the absorption of light at the lowest temperatures. Radio-active bodies, on the other hand, like radium, which are naturally self-luminous, maintain this luminosity unimpaired at the very lowest temperatures, and are still capable of inducing phosphorescence in bodies like the platino-cyanides. Some crystals become for a time self-luminous when cooled in liquid air or hydrogen, owing to the induced electric stimulation causing discharges between the crystal molecules. This phenomenon is very pronounced with nitrate of uranium and some platino-cyanides.

In conjunction with Prof. Fleming a long series of experiments was made on the electric and magnetic properties of bodies at low temperatures. The subjects that have been under investigation may be classified as follows: The Thermo-Electric Powers of Pure Metals; the Magnetic Properties of Iron and Steel; Dielectric Constants; the Magnetic and Electric Constants of Liquid Oxygen; Magnetic Susceptibility.

The investigations have shown that electric conductivity in pure metals varies almost inversely as the absolute temperature down to *minus* 200 degrees, but that this law is greatly affected by the presence of the most minute amount of impurity. Hence the results amount to a proof that electric resistance in pure metals is closely dependent upon the molecular or atomic motion which gives rise to temperature, and that the process by which the energy constituting what is called an electric current is dissipated essentially depends upon non-homogeneity of structure and upon the absolute temperature of the material. It might be inferred that at the zero of absolute temperature resistance would vanish altogether, and all pure metals become perfect conductors of electricity. This conclusion, however, has been rendered very doubtful by subsequent observations made at still lower temperatures, which appear to point to an ultimate finite resistance. Thus the temperature at which copper was assumed to have no resistance was *minus* 223 degrees, but that metal has been cooled to *minus* 253 degrees without getting rid of all resistance. The reduction in resistance of some of the metals at the boiling-point of hydrogen is very remarkable. Thus copper has only 1 per cent, gold and platinum 3 per cent.. and silver 4 per cent. of the resistance they possessed at zero C., but iron still retains 12 per cent. of its initial resistance. In the case of alloys and impure metals, cold brings about a much smaller decrease in resistivity, and in the case of carbon and insulators like gutta-percha, glass, ebonite, &c., their resistivity steadily increases. The enormous increase in resistance of bismuth when transversely magnetised and cooled was also discovered in the course of these experiments. The study of dielectric constants at low temperatures has resulted in the discovery of some interesting facts. A fundamental deduction from Maxwell's theory is that the square of the refractive index of a body should be the same number as its dielectric constant. So far, however, from this being the case generally, the exceptions are far more numerous than the coincidences. It has been shown in the case of many substances, such as ice and glass, that an increase in the frequency of the alternating electromotive force results in a reduction of the dielectric constant to a value more consistent with Maxwell's law. By experiments upon many substances it is shown that even a moderate increase of frequency brings the large dielectric constant to values quite near to that required by Maxwell's law. It was thus shown that low temperature has the same effect as high frequency in annulling the abnormal dielectric values. The exact measurement of the dielectric constant of liquid oxygen as well as its magnetic permeability, combined with the optical determination of the refractive index, showed that liquid oxygen strictly obeys Maxwell's electro-optic law even at very low electric frequencies. In magnetic work the result of greatest value is the proof that magnetic susceptibility varies inversely as the absolute temperature. This shows that the magnetisation of paramagnetic bodies is an affair of orientation of molecules, and it suggests that at the absolute zero all the feebly paramagnetic bodies will be strongly magnetic. The diamagnetism of bismuth was found to be increased at low temperatures. The magnetic moment of a steel magnet is temporarily increased by cooling in liquid air, but the increase seems to have reached a limit, because on further cooling to the temperature of liquid hydrogen hardly any further change was observed. The study of the thermo-electric relations of the metals at low temperatures resulted in a great extension of the well-known Tait Thermo-Electric Diagram. Tait found that the thermo-electric power of the metals could be expressed by a linear function of the absolute temperature, but at the extreme range of temperature now under consideration this law was found not to hold generally; and further, it appeared that many abrupt electric changes take place, which originate probably from specific molecular changes occurring in the metal. The thermo-electric neutral points of certain metals, such as lead and gold, which are located about or below the boiling-point of hydrogen, have been found to be a convenient means of defining specific temperatures in this exceptional part of the scale.

The effect of cold upon the life of living organisms is a matter of great intrinsic interest, as well as of wide theoretical importance. Experiment indicates that moderately high temperatures are much more fatal, at least to the lower forms of life, than are exceedingly low ones. Prof. McKendrick froze for an hour at a temperature of 182° C. samples of meat, milk, &c., in sealed tubes; when these were opened after being kept at blood heat for a few days, their contents were found to be quite putrid. More recently some more elaborate tests were carried out at the Jenner Institute of Preventive Medicine on a series of typical bacteria. These were exposed to the temperature of liquid air for twenty hours, but their vitality was not affected, their functional activities remained unimpaired, and the cultures which they yielded were normal in every respect. The same result was obtained when liquid hydrogen was substituted for air. A similar persistence of life in seeds has heen demonstrated even at the lowest temperatures; they were frozen for over a hundred hours in liquid air, at the instance of Messrs. Brown and Escombe, with no other result than to affect their protoplasm with a certain inertness, from which it recovered with warmth. Subsequently commercial samples of barley, pea, vegetable-marrow and mustard seeds were literally steeped for six hours in liquid hydrogen at the Royal Institution, yet when they were sown by Sir W. T. Thiselton-Dyer at Kew in the ordinary way, the proportion in which germination occurred was no less than in the other batches of the same seeds which had suffered no abnormal treatment. Bacteria are minute vegetable cells, the standard of measurement for which is the "mikron." Yet it has been found possible to completely triturate these microscopic cells, when the operation is carried out at the temperature of liquid air, the cells then being frozen into hard, breakable masses. The typhoid organism has been treated in this way, and the cell plasma obtained for the purpose of studying its toxic and immunising properties. It would hardly have been anticipated that liquid air should find such immediate application in biological research. A research by Prof. Macfadyen, just concluded, has shown that many varieties of micro-organisms can be exposed to the temperature of liquid air for a period of six months without any appreciable loss of vitality, although at such a temperature the ordinary chemical processes of the cell must cease. At such a temperature the cells cannot be said to be either alive or dead, in the ordinary acceptation of these words. It is a new and hitherto unobtained condition of living matter—a third state. A final instance of the application of the above methods may be given. Certain species of bacteria during the course of their vital processes are capable of emitting light. If, however, the cells be broken up at the temperature of liquid air, and the crushed contents brought to the ordinary temperature, the luminosity function is found to have disappeared. This points to the luminosity not being due to the action of a ferment—a "Luciferase"—but as being essentially bound up with the vital processes of the cells, and dependent for its production on the intact organisation of the cell. These attempts to study by frigorific methods the physiology of the cell have already yielded valuable and encouraging results, and it is to be hoped that this line of investigation will continue to be vigorously prosecuted at the Jenner Institute.

And now, to conclude an address which must have sorely taxed your patience, I may remind you that I commenced by referring to the plaint of Elizabethan science, that cold was not a natural available product. In the course of a long struggle with nature, man, by the application of intelligent and steady industry, has acquired a control over this agency which enables him to produce it at will, and with almost any degree of intensity, short of a limit defined by the very nature of things. But the success in working what appears, at first sight, to be a quarry of research that would soon suffer exhaustion, has only brought him to the threshold of new labyrinths, the entanglements of which frustrate, with a seemingly invulnerable complexity, the hopes of further progress. In a legitimate sense all genuine scientific workers feel that they are "the inheritors of unfulfilled renown." The battlefields of science are the centres of a perpetual warfare, in which there is no hope of final victory, although partial conquest is ever triumphantly encouraging the continuance of the disciplined and strenuous attack on the seemingly impregnable fortress of Nature. To serve in the scientifi army, to have shown some initiative, and to be rewarded by the consciousness that in the eyes of his comrades he bears the accredited accolade of successful endeavour, is enough to satisfy the legitimate ambition of every earnest student of Nature. The real warranty that the march of progress in the future will be as glorious as in the past lies in the perpetual reinforcement of the scientific ranks by recruits animated by such a spirit, and proud to obtain such a reward.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. JOHN PURSER, M.A., LL.D., M.R.I.A., PRESIDENT OF THE SECTION.

IN opening our proceedings to-day allow me at the outset to express my deep sense of the honour the Association has conferred upon me in asking me to preside over this Section.

My predecessors in this Chair have usually given you a survey of some department of Mathematics or Physics, tracing what had been already accomplished in that department and indicating the nature of the problems which still awaited solution.

May I crave your indulgence if I deviate from this course and, following the suggestion of some of my friends, take the opportunity of the Association meeting on Irish soil to give you a slight historical sketch of our Irish School of Mathematics and Physics?

In attempting such a review, for the sake of brevity as well as for other reasons, I shall confine it to the work of those who are no longer with us, and I would not carry it further back than the beginning of last century. This seems a natural starting point, as there was at that time a very marked revival of the study of science in the University of Dublin, a revival largely due to the influence of Provost Bartholomew Lloyd.

Lloyd won his Fellowship in Trinity College a few years before the century opened, and subsequently filled in succession the Chairs of Mathematics and Natural Philosophy. In both departments he imported a radical change into the methods of teaching. By his treatises on Analytical Geometry and on Mechanical Philosophy he introduced the study of what was then called the French Mathematics, in other words the more advanced Analytic Methods, which were in use on the Continent. In 1831 he was appointed Provost of the College, and his tenure of the office, though brief, was signalised by many important improvements and new developments effected in the University teaching.

Dr. Bartholomew Lloyd was President of one of the earliest Meetings of this Association, that held in Dublin in 1835.

His son, Dr. Humphrey Lloyd, had a course which was a singularly close parallel to his father's.

He won his Fellowship in 1824, and succeeded his father in the Chair of Natural Philosophy. He also was afterwards appointed Provost, and he too presided over another Dublin Meeting of this Association, that held in 1857. He also, in this again following in his father's steps, wrote important works on different branches of Physics; "Light and Vision," a systematic treatise on plane as distinct from physical optics, "Lectures on the Wave Theory of Light," and lastly a treatise on "Magnetism."

It is, perhaps, in connection with this latter subject that his most important work was done. He made in association with Sabine an elaborate series of observations on terrestrial magnetism in twenty-four stations in various parts of Ireland, and when subsequently, at the instance of your Association and of the Royal Society, the Government established magnetic observatories in different parts of the world, it was Lloyd who was entrusted with the task of drawing up the manual of instructions for the observers and of receiving their reports.

In the interval between the two Lloyds another name claims attention. Dr. Romney Robinson occupied during an exceptionally long life a much honoured and influential position amongst men of science. It was in this city he received his early education, for when young Robinson was only nine years of age his father had occasion to move to Belfast, and he placed his son under Dr. Bruce, a well-known schoolmaster of those days. Robinson was afterwards sent to Trinity College, and after a distinguished course was elected to a Fellowship in 1814. For some years he lectured in college as Deputy Professor of Natural Philosophy. He relinquished his Fellowship on obtaining a College living, and a few years later was appointed Astronomer in charge of the Armagh Observatory. The results of his observations were considered so valuable as to be used by the German astronomer Argelander in determining the proper motions of stars. The range, however, of his published papers was by no means confined to Astronomy, but extended to the most varied subjects, Heat, Electricity, Magnetism, Turbines, Air-pumps, Fog-signals, and others. He is best known to the general public as the inventor of the Cup Anemometer. He was chosen to preside over the Birmingham Meeting of this Association in 1849.

Robinson was intimately associated with Lord Rosse and keenly interested in the experiments which culminated in the construction of the great reflector in Parsonstown. This naturally leads us to speak of Lord Rosse himself. Few scientific achievements took a greater hold upon the public mind than the successful completion of his great telescope. Only those who have read in Lord Rosse's own papers the description of the many difficulties he had to contend with in forging and polishing that wonderful speculum, harder than steel yet more brittle than glass, can adequately appreciate the patience and resource with which those difficulties were successively overcome.

Of the results obtained with this instrument the most notable were in the observation of the Nebulæ, a department where its unsurpassed power of light-concentration came fully into play. No doubt at the time public attention was most excited by the resolution of a number of hitherto supposed nebulæ into star clusters, leading to the premature conclusion in the minds of those less instructed that all the nebulæ might ultimately be so resolved. To us, however, a far greater interest attaches to the observation of the structure of what we now know to be genuine nebulæ, especially the great discovery that these had in many cases a peculiar spiral form. All previous telescopes had failed to detect this spiral character; but the drawings taken by Lord Rosse and his assistants put this feature beyond question, and these have been fully confirmed in recent years, when more accurate delineations were obtained by photography. I need not dwell upon the significance of this form, indicating, as it does, a rotatory movement in these mighty masses and fitting in with, if not actually confirming, Laplace's Nebular Hypothesis.

Sir William Rowan Hamilton was undoubtedly the most striking figure in the annals of the Dublin School of Mathematics. *In limine* we must make good our right to call him an Irishman, for his greatest admirer and disciple, Prof. Tait, has claimed him for a countryman of his own, asserting that Hamilton's grandfather was a Scotchman who migrated to Dublin with his two young sons. That this was a complete misconception has been abundantly proved by the careful investigations of his friend and biographer, Dr. R. P. Graves, who shows conclusively that the only known strain of Scotch blood in Hamilton came through his grandmother, who was the daughter of a minister of the Scottish Kirk.

It is interesting to find how early Hamilton's remarkable mental powers began to show themselves. Dr. Graves has given us a letter from his mother in which she writes to her sister of the marvellous precocity of her little four-year-old boy, telling how "he reads Latin, Greek, and Hebrew."

His mental development did not belie these early indications, for at the age of thirteen, thanks to the teaching and care of his uncle, who was a most extraordinary linguist, he had not only acquired a considerable knowledge of the classics and the modern European languages, but also attained some proficiency in Arabic, Sanscrit and Persian. His mathematical studies, on the other hand, appear to have been carried on without help from anyone, and it is noteworthy that he does not seem to have used common text-books, but to have gone direct to the great original authors; *e.g.*, he read his algebra in Newton's "Arithmetica Universalis"; while at the age of fifteen he set himself to read the "Principia," and two years later began a systematic study of Laplace's "Mécanique Céleste." His own estimate of his powers may be gathered from a characteristic letter to his sister written just after he had entered Trinity College:—

"One thing only have I to regret in the direction of my studies, that they should be diverted—or rather rudely forced—by the College course from their natural bent and favourite channel. That bent, you know, is science—science in its most exalted heights, in its most secret recesses. It has so captivated me, so seized on, I may say, my affections that my attention to classical studies is an effort and an irksome one; and I own that, before I entered College, I did not hope that in them I would rise above mediocrity. My success surprised me, but it has also given me a spur by holding out a prospect that even in the less agreeable part of my business I may hope still to succeed."

This letter is interesting as indicating on Hamilton's part a consciousness wherein lay his real strength and vocation. Not that his interest in literature ever abated. To the last he loved to try his hand at poetical composition, frequently inserting in his letters to his friends sonnets of his own.

He knew Wordsworth intimately, and the poet, to whom he sent some of his productions, gives him the following candid advice:—

"It would be insincere not to say that something of a style more terse and a harmony more accurately balanced must be acquired before the bodily form of your verses will be quite worthy of their living souls. You are perfectly aware of this, though perhaps not in an equal degree with myself; nor is it desirable you should be, for it might tempt you to labour which would divert you from subjects of infinitely greater importance."

Hamilton was first in his College classes in every subject and at every examination, and it was fully expected that he would carry off both the medals in Mathematics and Classics at his Degree when the following circumstances suddenly changed all his plans. Dr. Brinkley, the Professor of Astronomy in the University, was appointed to a Bishopric, and Hamilton, though still an undergraduate, was invited to offer himself for the vacant Chair. Sir George Airy and more than one of the Fellows of Trinity were also candidates, but Hamilton was unanimously elected.

His career as an original author dates from this time, for immediately after his appointment he communicated to the Royal Irish Academy the first of three remarkable papers on "Systems of Rays."

Two striking features may be observed in these papers, as indeed in all his scientific memoirs: the generality and comprehensiveness with which he states his object at the outset and the confidence with which he follows the bold and original lines of treatment which he lays down for himself, and closely connected with this, the determination not to be baffled by any laboriousness of calculations which the application of his method may involve him in. In his first paper he begins by examining what happens to a system of rays of light emanating from a point and subjected to any number of reflections at curved surfaces. He establishes the theorem that such a system will be cut orthogonally by a system of surfaces, the length of the path measured from the original source to any of these surfaces being the same for all the rays. The proof he gives of this theorem is so simple that it now seems almost axiomatic; but it is curious that Malus, who had made the laws of Light his special study, though he suspected that the theorem ought to hold, yet found himself unable to establish it.

Hamilton, now considering the length of the path to any point as a function of the coordinates of that point, and denoting this function by V, proves that V satisfies a simple partial differential equation of the first order and proceeds to show the important part the function V plays in the theory.

He goes on to prove generally that if we are dealing, not with right lines, that is, with paths, for which as between any two points $\int ds$ is a minimum, but with curved paths for which $\int \mu ds$ is a minimum (where μ is a function of the coordinates), and a system of such paths be drawn through a given point, O, the system of surfaces V = const. will still cut all the paths at right angles. If we adopt the emission theory of Light, and we take for μ the velocity of Light, V becomes "the Action," and the minimum property which the paths satisfy is the principle of "Least Action." If, on the other hand, we adopt the undulatory theory, and we take for μ the reciprocal of the velocity, the minimum property becomes the principle of "Least Time." Thus Hamilton shows that, by altering the significance of μ, his method applies to either theory.

Introducing the further conception that μ depends, not only on the coordinates of the point, but also on the direction-angles of the ray, he is able to apply his reasoning to rays passing through a crystal. He gives by his method a new and interesting proof of the equation of Fresnel's wave-surface, and arrives at the conclusion, hitherto unnoticed by mathematicians, that this wave-surface possesses four conical cusps and also four special tangent planes, each of which touches the surface, not in one point only, but in an infinite system of points lying in a circle. The physical significance of these theorems is what is known as Conical Refraction.

Having drawn this inference from his mathematical analysis, Hamilton wrote to his friend Dr. Lloyd and asked him to verify it by actual observation, and accordingly Hamilton's paper in the *Transactions* of the Academy is accompanied by another from Lloyd, describing the beautiful arrangements by which he had succeeded in verifying this remarkable phenomenon in both its varieties.

This striking instance of scientific prediction naturally made a great sensation at the time, appealing, as it did, to a much larger public than the few select mathematicians who were capable of mastering the elaborate treatise on "Systems of Rays."

The experimental skill that was required to obtain these results may be realised from the circumstance that as I have been told the French physicists found themselves unable to repeat the experiment till Lloyd himself went over to Paris with his instruments and showed them the way.

Hamilton was so well satisfied with the success of his new method in dealing with the problems presented by the propagation of Light that full of enthusiasm he proceeded to apply a generalised form of the same method in the investigations of the motion of any material system, and a paper of his was read before the Royal Society in 1834 with the following title: "On a general method in Dynamics by which the Study of the Motions of all free systems of attracting or repelling points is reduced to the Search and Differentiation of one Central Relation, or Characteristic Function"

To show the importance attached by the most competent judges to Hamilton's work in this field of Theoretical Dynamics, we cannot do better than quote the words of his great German contemporary Jacobi, who afterwards himself added to the new theory such valuable developments.

Jacobi writes as follows:—"If a free system of material points is acted on by no other forces than such as arise from their mutual attraction or repulsion, the differential equations of their motion can be represented in a simple manner by means of the partial differential coefficients of a single function of the coordinates. Lagrange, who first made this important observation, at the same time showed that this form of the differential equations possesses great importance for Analytical Mechanics. The marked attention, therefore, of mathematicians could not fail to be aroused when Herr Hamilton, Professor of Astronomy in Dublin, indicated in the *Philosophical Transactions* that in the Mechanical problem referred to all the integral equations of motion might be represented in just as simple a manner by means of the Partial Differential Coefficients of a single function. This is undoubtedly the most considerable extension which Analytical Mechanics has received since Lagrange."

It will be of interest to the Section to recall the fact that Hamilton and Jacobi met each other for the first and I fancy the only time at a meeting of this Association, held in Manchester in 1842, at which meeting Jacobi, addressing this Section, called Hamilton "le Lagrange de votre pays."

The last third of Hamilton's life was mainly devoted to the development of his Quaternion Calculus. As early as 1828 his Class Fellow, J. T. Graves, who had been working at the theory of the use of imaginary quantities in Mathematics, wrote an essay on Imaginary Logarithms which he wished to get printed by the Royal Society. There appears to have been some hesitation amongst the leading mathematicians in the Society, notably, Herschel and Peacock, about publishing Graves' paper, as they felt dubious about the accuracy of his reasoning. Hamilton heard of this and wrote earnestly to Herschel defending his friend's conclusions, and it seems as if his generous desire to help his friend first set his own mind working in this direction.

For years his busy brain in the midst of all his other work kept pondering over this question of the interpretation of the imaginary, and he has left us in his "Lectures on Quaternions" an elaborate account of the many systems he devised.

It was only in 1843, fifteen years later, that he first invented the celebrated laws of combination of the quadrantal versors of the Quaternion Calculus. Argand, Cauchy, and others had proposed for space of two dimensions the theory now known as that of the Complex Variable. For them $x+iy$ meant the vector to the point xy, and the product of two vectors meant a new vector of the same form, the only law required being that i operating upon i was always equivalent to -1.

Many attempts had been made to form on similar lines a Calculus which should apply to space of three dimensions; but so far all such attempts had proved unsuccessful, the laws by which the new symbols acted upon one another leading to results hopelessly involved. It was here that Hamilton's wonderful faculty of scientific imagination came into play. He proposed that

vector should be denoted by $ix+jy+kz$. As in the theory of he complex variable in two dimensions the result of any number of successive operations always preserved the fundamental type $a+ib$, so it was desirable that the result of the successive operations of his vectors should issue in an equally simple fundamental type. This end he found he could attain if he discarded the commutative principle which hitherto had barred his own progress and that of others, yet preserving the distributive and associative principles, and finally one happy evening he arrived at the beautifully simple laws by which the symbols of this Calculus act upon each other; that not only $i^2=j^2=k^2=-1$, but also that $ij=-ji=k$, $jk=-kj=i$, $ki=-ik=j$.

Though it was thus—as the product, that is, of two vectors—that the Quaternion first presented itself to Hamilton, he of course saw that it immediately followed that it might be regarded as the ratio of two vectors, in other words the operation which turned one vector into another. In fact in the more synthetic exposition which is contained in "The Elements" he makes this latter the starting definition of the Quaternion.

It is noteworthy that this, the more complete and systematic presentation of the subject by its illustrious author, may be said to owe its origin to the keen interest my predecessor, Prof. Tait, took in the new Calculus, of which, as you know, he ever afterwards remained the most ardent champion. This interest led him to seek from Dr. Andrews an introduction to Hamilton, and the encouragement came to Hamilton at an opportune moment, for he wrote:—

"It was useful to me to have my attention recalled to the whole subject of the Quaternions, which I had been almost trying to forget, partly under the impression that nobody cared or would soon care about them. The result seems likely to be that I shall go on to write some such 'Manual,' but necessarily a very short one."

The "Manual" thus foreshadowed became the voluminous treatise "The Elements of Quaternions."

Those interested in the future of Quaternions will have welcomed the new edition of this work brought out by the present occupant of Hamilton's Chair, Prof. Charles Joly, who has himself also added some remarkable developments to one branch of the subject, the Theory of the Linear Vector Equation.

Hamilton's Quaternions may be viewed in two lights, as a development of the logic and philosophy of symbols in their relation to space of three dimensions and also as an instrument of research in Geometry and Physics. In the former aspect, the Quaternions will ever remain a splendid monument of the imagination and genius of its inventor. In the latter point of view, that is. when we come to regard it as a working calculus, it would be premature as yet to fix the place it will ultimately occupy.

A few years after Hamilton had entered upon his scientific career, James MacCullagh won his Fellowship in Trinity College. After an interval of three years he was appointed Professor of Mathematics, and eight years later succeeded Dr. Lloyd in the Chair of Natural Philosophy. It would be difficult to overestimate the stimulating effect of MacCullagh's lectures as Professor upon the Mathematical School. Many of those whose names stand out afterwards—such men as Jellett, Michael and William Roberts, Haughton, Townsend and our present honoured Provost—were MacCullagh's pupils. To the present day the tradition still lingers in Trinity College of the impression MacCullagh made upon the minds of those with whom he came in contact.

When, passing from his influence as a teacher, we come to examine his own original work, we find that this naturally divides itself into two departments, the first embracing Geometry and that part of the field of Mathematical Physics which most resembles Geometry, that in which the fundamental principles are entirely agreed upon; the second his work in Physical Optics, where he has to imagine new principles which, mathematically developed, should correlate the empirical laws hitherto obtained and be capable of verification by experiment.

Of the first class we have his studies in "Surfaces of the Second Degree." The most striking result he here obtained was the discovery of the modular generation of the quadric, thus extending to surfaces the focus-and-directrix property of the conic in plano. We are also indebted to him for some very elegant theorems in the theory of confocal quadrics, a subject to which he devoted much attention. He likewise gave a course of lectures containing a masterly discussion and geometrical presentment of the motion of a rigid body round a fixed point not acted on by external forces.

At the very outset of his career as an original author he seems to have been attracted by the theory of Light. To understand the ardour with which MacCullagh and his contemporaries devoted their mathematical powers to Physical Optics, we must endeavour to recall the circumstances of the time. The celebrated memoirs of Fresnel had recently appeared. In these he had proved, following Young, that the ethereal vibrations which constitute Light must be in the plane of the wave-front; that a beam of polarised light was simply a system of parallel waves in which these transverse vibrations were all in one direction. He had applied the theory of the ellipsoid to prove that there were three directions in a crystal in which the restitution-force coincided with the direction of the vibrations; that in the plane of every wave there are two directions along which, if a particle vibrate, the component of the restitution-force resolved in the plane of the wave will be along the direction of displacement. He had also from these principles deduced the equation of his famous wave-surface.

How much the work of Fresnel filled the imagination of scientific men in those days may be seen from the enthusiastic language which the sober-minded Dr. Humphrey Lloyd allows himself to use about him in his valuable report on Physical Optics, which he wrote for this Association in 1834.

In passing I would say that the name of Fresnel reminds us of the loss Science, and especially this Section, has sustained since we last met in the death of that illustrious French physicist who devoted his life with such ardour and success to the same field of research—Alfred Cornu. Those of us who had the privilege of being present will recall with a sad pleasure the beautiful address he gave us in Cambridge on the Wave Theory of Light on the occasion of Sir George Stokes' jubilee.

Fresnel in his analysis had assumed that when the molecules of the ether are disturbed by the passage of a wave the force of restitution acting upon a molecule depends upon that molecule's absolute displacement. Cauchy and Neumann and, in England, Green, improved on Fresnel's reasoning, making this force depend, not on the absolute, but on the relative displacement; all these physicists, however, worked on the lines of endeavouring to form an explanation of the propagation of the waves of Light, by treating them as the waves in an elastic medium, akin in its properties to a solid medium in which the stresses depend on the deformation of the elements.

MacCullagh agreed with these others in making the forces of restitution depend on the relative displacements as expressed through a certain function V, which represented the potential energy of the medium. In the further development of the theory he, however, diverges from them and adopts a line of his own. Struck by the significance of the fact, to which he seems to have been the first to direct attention, that the vector whose components are

$$\frac{1}{2}\left(\frac{dv}{dz}-\frac{dw}{dy}\right),\ \frac{1}{2}\left(\frac{dw}{dx}-\frac{du}{dz}\right),\ \frac{1}{2}\left(\frac{du}{dy}-\frac{dv}{dx}\right),$$

which we now, of course, know as the vector of molecular rotational displacement, was, so to speak, a physical vector, independent of the choice of our axes of coordinates, he was led to the idea of choosing for the form of V that of a homogeneous quadric in these three components. It must be admitted that the reasoning by which he attempts to prove the necessity of this assumption is eminently unsatisfactory, and that the assumption itself lay open to an apparently fatal objection urged later by Stokes, that of neglecting to secure the equilibrium of the element of the medium quoad moments.

Having, however, adopted this form of V. MacCullagh proceeds (making the assumption that while the elasticity of the medium varied the density was everywhere the same), by processes of remarkable elegance and simplicity, to develop the laws of wave propagation in a crystal, thus verifying the wave-surface of Fresnel, while at the same time he found himself able to satisfy completely the requirements at the limits. He could also point to experience, *e.g.*, the experiments of Brewster and Seebeck, as justifying the simple and beautiful laws which he had succeeded in obtaining.

Nevertheless the force of Stokes' objection was felt to be so strong that one who reviewed the subject, say thirty years ago, would have regarded MacCullagh's work in Optics as presenting indeed opportunities for beautiful mathematical developments, but lacking sound physical basis.

The publication, however, of the epoch-making treatise of Maxwell on Electricity and Magnetism entirely changed the aspect of the question, and in particular threw a new light on MacCullagh's assumption. FitzGerald, in 1879, pointed out that the Potential Energy, which in Maxwell's theory was equivalent to the electrostatic energy, really was a quadratic function of three variables, which answered to the components of MacCullagh's molecular rotation, and accordingly led to the same differential equations of the motion as MacCullagh had deduced.

Subsequently Larmor, in his remarkable investigation of the Dynamical Theory of the Electric and Luminiferous Ether, deliberately reconsiders MacCullagh's position, finds in fact in his equations the starting point of his own theory. He points out the real significance of MacCullagh's function V; that it corresponds to a stress-strain system, but one of a very novel type; one in which the stresses depend entirely on the rotational displacements of the molecules, and are otherwise absolutely unaffected by the ordinary deformation-strains. He further shows that the difficulty under which MacCullagh's theory laboured, that it did not provide for the rotatory equilibrium of the element, could be removed if we allowed ourselves to assume the existence of a hidden torque acting on each element.

As I understand the advocates of this theory, they maintain that an important step has been made, even though in the present state of our knowledge we may not be able to account for the existence of this hidden torque. They point out, however, that such a torque is at least not inconceivable, whether its explanation be sought in concealed kinetic phenomena, as in Lord Kelvin's material gyrostatically constituted medium, or in quasi-magnetic forces supposed to reside in the ethereal elements.

Should this theory of a rotationally elastic ether obtain final acceptance, it will of course be a matter of congratulation to MacCullagh's countrymen to find that his labours, in this, perhaps the most important field of his researches, have not been thrown away; that they represent no mere play of elegant mathematical analysis, but a real step in the progress of physical science.

A few years after MacCullagh, two other well-known men, whose names for half a century were associated with the Mathematical School in Dublin, were elected Fellows—Andrew Searle Hart, afterwards Sir Andrew Hart, and Charles Graves, subsequently Bishop of Limerick. They won their Fellowships in two successive years, and both lived to an advanced age.

Hart had a great reputation as a geometer. His examination papers were specially noted for the number of original problems they contained. As specimens of his work we may instance the following. Extending Feuerbach's theorem for the nine-point circle, Hart showed that the circles which touch three given circles can be distributed into sets of four all touched by the same circle. He also showed that Poncelet's beautiful porism for coaxal circles in plano held for the surface of an ellipsoid, if we replace the rectilineal polygons by geodetic polygons and the coaxal circles by lines of curvature.

Graves became Professor of Mathematics on MacCullagh's resigning the Chair in 1843. He was largely influenced by the writings of Chasles, of whose two memoirs on Cones and Spherical Conics he published a translation. In this were incorporated valuable original additions of his own, amongst others the remarkable theorem that if two spherical ellipses are confocal the sum of the tangents drawn to the inner from any point of the outer exceeds the intercepted arc between the points of contact by a constant length, a theorem which of course includes the corresponding proposition for confocals in plano. Graves was one of the first to apply the method of the Separation of Symbols to Differential Equations, and gave an elegant demonstration by this method of Jacobi's celebrated test for distinguishing between maxima and minima in the Calculus of Variations.

On the death of MacCullagh it was determined to strengthen the Natural Philosophy department by the establishment of a second Professorship in that subject, and Jellett, one of the ablest of MacCullagh's pupils, was appointed to the new Chair.

His first published work was his "Calculus of Variations," which at the time it was written constituted the only systematic English treatise on the subject. It is marked by that peculiar acuteness and power of fastening on essential points, whether for criticism or exposition, which was the author's leading characteristic. Apart from the excellent account he gives of the researches of Continental mathematicians, I would notice especially his most interesting chapters on the conditions of integrability and many valuable geometrical theorems on surfaces hence resulting. In discussing his more properly original work we may arrange it in three divisions: 1st, his papers on Elasticity; 2nd, that on the properties of Inextensible Surfaces; 3rd, those on the application of polarised light to the new subject of Chemical Equilibrium.

In taking up the problem of an elastic medium and the propagation of waves in such medium, Jellett follows the example of MacCullagh, who had made this subject one of special interest to the Dublin school. In these memoirs he draws attention to a remarkable difference in the mode of regarding the molecular constitution of the medium, a difference corresponding to what is now known as the distinction between the Rari-constant and Multi-constant theories. We may, Jellett points out, regard the action between two molecules as only conditioned by the relative position of these molecules, or as dependent also on the position of the neighbouring molecules. The first is termed by Jellett the hypothesis of independent action, and this he shows to lie at the basis of Cauchy's theory, whereas the theory of Green, the English elastician, essentially involves the second hypothesis which Jellett calls "modified action." He established in the same papers the important theorem that if a Work function exists the three directions of vibration, corresponding to a plane-wave, are rectangular, and *vice versâ*.

In his memoir on Inextensible Surfaces various interesting questions are discussed. He proves that in the case of a synclastic surface if a closed curve on the surface be held fixed, the entire surface will be immovable; that on the other hand on an anticlastic surface it is possible to draw a curve which may be held fixed without involving the immovability of the surface, the conditions being that the curve will be that formed by the successive elements of the inflectional tangents. The mathematical theory of such curves had been already studied, but Jellett seems to have been the first to signalise their importance in the theory of deformation, and, on account of the property referred to, he proposed to call them Curves of Flexure. It is interesting to remark that Maxwell was attracted by the same subject of Inextensible Surfaces, and in one of his earliest papers confirms by an entirely different method several of Jellett's conclusions.

At the close of Jellett's paper a remarkable proposition is laid down, apparently for the first time, that a closed oval surface cannot be inextensibly deformed; in other words, that if such a surface be perfectly inextensible it is also perfectly rigid. I think we must admit that the proof of this striking theorem offered by Jellett is by no means satisfactory. Subsequent attempts by others to establish this proposition can hardly be said to be more successful. But the fact that it can be rigorously proved true for a sphere or more generally for any ellipsoid seems to indicate that we have here to do with a real and important theorem, but one which needs, as is so often the case, to have the limits of its application more clearly defined.

Many experimental physicists will know Jellett best by the beautiful and delicate instrument he invented, "The Double-plane Analyser," an instrument which he devised in order to secure the more exact determination of the rotation of the plane of polarisation than could be obtained by the polariscopes hitherto in use. Jellett was actuated here by the consideration that he saw in this phenomenon of the rotation of the plane of polarisation a means of attacking the interesting problem of chemical equilibrium. Chemical equilibrium he defines thus: "Two or more substances may be said to be in chemical equilibrium, if they can be brought into chemical presence of each other (as in a solution) without the formation of any new compound or change in the amount of any of the former compounds which have thus been brought together." In a mixed solution of sundry bases and acids where all the possible salts are soluble, what are the proportions in which the acids are distributed amongst the bases? Such was Jellett's question, and in answering it he arrives by a remarkable train of quasi-mathematical reasoning at certain laws governing this distribution, and proceeds to establish the truth of these laws by observation with his new polariscope.

He also discusses in the same papers two alternative theories which we can hold of chemical combination, the "statical" and the "dynamical," and shows from the consideration of the number of equations which subsist that the "dynamical theory" is alone admissible.

When the Association met in Belfast twenty-eight years ago Dr. Jellett occupied this Chair, and at the close of his Address, in which he took for his subject certain fresh applications of Mathematical Analysis to Physical Science, he touched upon these very researches in which he was at the time engaged.

All old Trinity men would think this enumeration incomplete if it did not refer to the wonderfully active animating presence of Samuel Haughton. He also directed his energies in the first instance to the subject of Elasticity, on which he wrote several important memoirs, endeavouring to formulate a system of laws by which he might be able to explain the propagation of Light. But apparently discouraged by the extreme difficulty of the problem his versatile brain turned soon to quite other branches of science—to Physical Geology, then to Physiology and Medical Science, and in fact in his later work he passes out of the cognisance of Section A.

Of the pure mathematicians trained under MacCullagh two of the most eminent were the twin brothers Michael and William Roberts. Strikingly alike in their personal appearance they were in my student days two of the best known figures in the Courts of Trinity.

In his geometrical work Michael Roberts pursued the fruitful lines of research started by Chasles and followed up by MacCullagh in the study of quadric surfaces, and it fell to his lot to discover some most remarkable theorems on the relations of the geodetics on the surface to the lines of curvature; theorems indeed to which the author would have been justified in applying words which Gauss used of a great theorem of his own:

"Theoremata quæ ni fallimur ad elegantissima referenda esse videntur."

Joachimsthal had shown that the first integral of the equation of the geodetics on an ellipsoid could be thrown into the well-known form PD = constant. Michael Roberts now showed that the geodetics, which issue in all directions from an umbilic, pass through the opposite umbilic where they meet again by paths of equal length; that the lines of curvature considered with respect to two interior umbilics possess properties closely analogous to those of the plane conic with respect to its foci; that if such umbilics A and B be joined by geodetics to any point P on a given line of curvature they make equal angles with such line, and consequently that as P moves along the line of curvature, either PA + PB or PA − PB remains constant, so that if the ends of a string be fastened at the two umbilics and a style move over the surface of the ellipsoid, keeping the string stretched, the style will describe a line of curvature. Another remarkable analogue he proved was the following: that as in a plane conic if a point P on the curve be joined to the foci A and B,

$$\tan \tfrac{1}{2}(PAB) \tan \tfrac{1}{2}(PBA) = \text{const.}$$
$$\text{or } \tan \tfrac{1}{2}(PAB)/\tan \tfrac{1}{2}(PBA) = \text{const.}$$

so precisely the same relation holds for a line of curvature on the quadric, replacing the foci by the umbilics and the right lines by geodetics.

Sir Andrew Hart made a valuable contribution to the subject by investigating the relation between the angles which an umbilicar geodetic makes with the principal plane when it leaves the umbilic and when it returns to it again after going the circuit of the surface. He proved that if ω and ω' be these angles, $\frac{\tan \frac{1}{2}\omega'}{\tan \frac{1}{2}\omega}$ can be expressed by means of complete elliptic integrals independent of ω. This is interesting, as it shows that such a geodetic is not a finite closed curve, but that it crosses itself over and over again at the umbilics, the successive values of $\tan \frac{1}{2}\omega$ forming a geometric series.

To Michael Roberts is also due much important work in the department of pure analysis—notably, in modern Algebra his method of deriving Covariants, and the investigation of their relations by means of their sources, and in the theory of Abelian integrals his construction (following the method of Jacobi) of a Trigonometry of the hyperelliptic functions.

His brother William Roberts is perhaps best known for some of the investigations he carried out by means of elliptic coordinates. For example, he applied them to Fresnel's wave-surface, and showed that the two sheets of the surface can be expressed in the simple forms

$$\lambda^2 + \nu^2 = a^2 + b^2 - c^2 \text{ and } \lambda^2 + \mu^2 = a^2 + b^2 - c^2.$$

By following the same method he succeeded also in adding an interesting new triple system of orthogonal surfaces to those already known.

Richard Townsend was another of the Fellows of Trinity of MacCullagh's school. He was known to us in College in my day as the great expositor of the new geometry of Anharmonics and Involution. He wrote many valuable original papers, but it was as a lecturer he was most remarkable. I never met a teacher so enthusiastic or one who seemed to enjoy teaching more thoroughly.

He inspired his pupils with much of his own ardour, and it is greatly owing to Townsend's influence that the old name Trinity had for the study of Geometry was so well kept up in his day.

He published in the latter part of his life an extensive treatise on Modern Geometry, which did good service in presenting the subject in the light of an organised system and not as a collection of isolated problems.

In this connection I must not omit to mention one of our most original Irish geometers of recent days, Dr. John Casey. Where Casey learnt his Mathematics is indeed a marvel. Up to middle life he was engaged in the engrossing labour of a schoolmaster in Kilkenny under the National Board of Education. It was not till he was nearly forty that by the advice of Townsend, to whom he used to send up some of his ingenious geometrical solutions, he moved up to Dublin and entered Trinity College. Of his original papers his best known are those on Bicircular Quartics and Cyclides.

In elementary Geometry we owe to him a very elegant extension of Ptolemy's famous theorem that for four points, A B C D, on a circle AC.BD = AB CD + AD.BC. Casey shows that the same equation is true if we replace the four points by four circles touching a common circle and the lines joining the points by the common tangents to the circles. He acquired so high a repute both as a teacher and as a writer that he was offered and accepted the post of Professor of Mathematics in the Catholic University.

It is not yet two years since George FitzGerald was taken from us. The many loving tributes to his memory which appeared in the scientific journals after his death reveal to us how deep and widespread his loss was felt to be, but it is in Ireland this loss is most serious. As long as he lived and worked, our country could claim to own one of the foremost members of that select band who are endeavouring to wrest from Nature her inmost secrets.

You knew how sedulous an attendant he was of the meetings of this Section, and Trinity College never sent you a representative of whom she had more reason to be proud, for he has done more than any of her sons for many years to maintain the reputation of her scientific school. This he has brought about, not by his writings only, able and original as these were, but also by the encouragement and stimulus he gave the younger men he gathered round him, and the self-forgetful readiness with which he gave all the help he could to those who in any measure shared his own genuine love for science.

You will all rejoice that we are now in possession of a volume containing a complete collection of FitzGerald's scientific papers. I am sure he himself could not have wished for a better chronicler of his life and labour than his intimate friend Dr. Larmor, more especially as Dr. Larmor's own far-reaching speculations on the great mystery of the ether qualify him in a very peculiar manner to appreciate the work of his fellow-physicist. The admirable analysis of that work in the opening pages of this volume renders any further account of it on my part completely unnecessary.

A few months before FitzGerald's death there passed away one of his most distinguished pupils, Thomas Preston. Though cut off so young he had already done much work, and of a quality which raised high expectations of his future. His treatises on Light and on Heat are to be noted, not merely for the excellent account they give of the recent additions to the subjects treated, but for the thoughtful and philosophic spirit in which the whole is presented. It was, however, his experimental researches which most excited attention, more particularly those on the action on Light of a strong electro-magnetic field and the fine experiments in which he extended beyond any observations hitherto made the analysis of the Zeeman effect.

Of two others I have yet to speak, and these were emphatically representatives of this city and of the College in whose Halls we are meeting to-day—Thomas Andrews and James Thomson. It would be difficult to describe adequately all the phases of so manifold an activity as that of Dr. Andrews. As one long associated with him as a colleague I would bear testimony to one side of his life-work—the potent influence he

exercised in this College in its earlier years as a skilful pilot guiding the ship till it was well out of port. His high ideal of the function it should discharge in the education of the country and the practical zeal and ability which he ever brought to bear on the administration of our affairs contributed in no small measure to place the College in the assured position it occupies to-day.

On his great physical and chemical investigations it is happily the less necessary for me to touch, as they have been so fully brought before you by our President in his opening Address; and as regards the most important of these researches, those on the continuity of the Liquid and Gaseous states, no one assuredly could have more fitly expounded them than one who has himself pressed forward with such splendid success in the paths which Andrews opened up.

I have always considered that Andrews, through the long course of these later researches, was most fortunate in having near at hand such a friend as James Thomson; not that he was a collaborator—for Andrews did all this work unaided—but that Thomson gave him throughout that best of all encouragement which consists in enlightened appreciation of the importance of the results he was obtaining and of their inner meaning and significance.

Of Thomson himself what shall I say? Of all the scientific men I have come across he perhaps most fulfilled the idea of a philosopher, his ever-working brain ever seeking out causes, ever pondering on the why and the wherefore of the unexplained.

One of his earliest investigations is perhaps the best known, that in which, basing his reasoning on Carnot's principle, he demonstrates the effect of pressure in lowering the freezing-point of water, and in which he gave at the same time a numerical estimate to this effect.

This discovery was of great practical import, for, small as the effect was, it enabled him to explain fully the rationale of the plasticity of ice.

Forbes had already shown that the motion of glaciers depended upon a plastic or viscous quality in the ice. It remained for Thomson, by the aid of his newly discovered principle, to go a step further and account for this plasticity.

It is interesting to note that the questions which led to some of his most valuable investigations seem to have been started by the filial task he took upon himself of re-editing his father's educational text-books. It was, for example, the revision of a chapter in his father's Geography which I believe led him to examine more thoroughly into Hadley's theory of the Trade winds, and to make the following important addition to that theory. He showed that while in the tropical latitudes, say of our northern hemisphere, two currents would satisfy all the conditions, *i.e.*, the Trade wind blowing from N.E. to S.W. in the lower regions of the atmosphere, and the return current in the upper regions, on the other hand that in the temperate latitudes there must be three currents at different elevations; that the uppermost and the lowest of these have a movement towards the Pole, but in the middle regions of the atmosphere between these there must be a large return current from the Pole, and that the prevailing motions of all three currents would be from west to east.

Thomson was particularly successful in his treatment of this and other questions of fluid motion. He was not familiar with the technique of the higher mathematics, and on this very account was not tempted, as so many mathematical experts are, to assume impossible conditions in order to bring the problems within reach of their algebraic analysis; but for all that his mind was eminently of a mathematical cast. He is never vague or loose in his reasoning, and he had a wonderfully tenacious grasp of physical principles. The result was that he has succeeded in finding out the key to some of the most curious phenomena in the motions of fluids.

I may give as a typical instance of his line of reasoning his beautiful explanation of the action of the water of a river flowing round a bend. He saw clearly that from true dynamical principles the flow of the water must be most rapid near the inner bank, and the question which presented itself to his mind was why then the inner bank was not worn away. The answer he showed to consist in the friction of the bed checking the velocity of the lowest stratum of the water. The effect of this he proves to be that an under-current is produced in this stratum across the bed of the river from the outer towards the inner bank, a current which does two things: it carries sand and detritus and deposits them on the inner bank; and, since the water in this current has to rise vertically to the surface when it reaches this bank, it thus protects it from the scour.

In a review of Thomson's work we should emphasise his constant endeavour, whether in Mathematics or Physics, to attain clear conceptions of fundamental principles. This showed itself in the various innovations in nomenclature he introduced. Many of the new words he coined, "radian," "numeric," "torque," "interface," "clinure," "posure," &c., are great helps both in thinking and teaching.

The same determination at any cost of hard thinking to arrive at clearness in regard to fundamental principles is strikingly evidenced by one of his later papers, that on the "Law of Inertia and the Principle of Chronometry," which is a most searching discussion of the true significance of Newton's first and second laws of motion.

I must now close this review. I shall be glad if I have succeeded, however imperfectly, in giving you some impression of our Irish schools of Mathematics and Physics, of the workers and of the sources from which they drew their inspiration. There surely never was a time when the problems presented to the mathematician by Physical Science were more interesting; never a time when Science for its onward progress stood more in need of those gifted ones who combine clearness of thought with imagination and hopeful courage. Let us hope that amongst these in this new century, others of our countrymen may be found not unworthy to have their names inscribed in the roll which contains those of Hamilton and MacCullagh, of Andrews and Thomson.

NOTES.

WE record, with very deep regret, the death of Prof. Virchow, on September 5, in his eighty-first year. The State funeral accorded to Prof. Virchow took place in Berlin on Tuesday. Among those present were the Prussian Ministers of Education and Finance, the Foreign Secretary, the Chief Burgomaster of Berlin, and numerous representatives of Berlin and other universities, and of learned and scientific societies—both German and foreign. After the funeral service, orations were delivered, in which Prof. Virchow was considered as man of science, politician and municipal reformer. At the meeting of the Paris Academy of Sciences on Monday, a eulogy on Prof. Virchow was delivered by M. Bouchard.

WE have also to announce the death of Sir Frederic Abel, on September 6, in his seventy-sixth year.

THE next meeting of the Australasian Association is to be held in Dunedin, New Zealand, in January, 1904, and the following have been appointed presidents of sections:—B—Chemistry: J. Brownlie Henderson, Brisbane. C—Geology and mineralogy: W. H. Twelvetrees, Hobart. D—Biology: Colonel W. V. Legge, R.A., Hobart. E—Geography: Prof. J. W. Gregory, Melbourne. F—Anthropology and philology: A. W. Howitt, Melbourne. G—Economics, subsection 2, agriculture: J. D. Towar, Roseworthy, South Australia. H—Architecture, engineering and mining: H. Deane, Sydney. I—Sanitary science and hygiene: Dr. Frank Tidswell, Sydney. J—Mental science and education: John Shirley, Brisbane.

THE annual congress of the Sanitary Institute was opened at Manchester on Tuesday last, when some two thousand delegates were present from all parts of the country.

IN connection with the celebration of the 100th anniversary of the birth of Niels Henrik Abel, now in progress at Christiania, twenty-nine foreign men of science on Saturday last received the degree of Doctor, *Honoris Causa*; among the number were Lord Kelvin, Lord Rayleigh, Sir George Stokes, Prof. G. H. Darwin, Prof. Forsyth, and the Rev. George Salmon, Provost of Trinity College, Dublin.

THE Punjab Government has, according to the special Indian correspondents of the *Lancet* and the *British Medical Journal*,

submitted a great project to the Government of India and the Secretary of State for sanction in order to grapple with the expected outbreak of plague during the coming winter. The disease has rapidly grown in intensity in the province. Commencing in 1899–1900 with two districts and one native State affected and 530 deaths, followed by the next year with seven districts and two native States affected and 6399 deaths, it had last year no less than twenty-three districts and nine native States attacked and more than 200,000 deaths. Experience has shown that segregation of the sick is out of the question, that evacuation of dwellings even in villages can only be partial, and that disinfection is practically useless. This being so, the Punjab Government now proposes to offer universal voluntary inoculation. Arrangements are to be made to perform six and a half million inoculations between now and January next. The scheme is expected to cost more than Rs. 8 lakhs.

INFORMATION has been received through Reuter's Agency concerning the progress which has been made by the commission sent out to inquire into the mysterious "sleeping sickness" of Uganda. The three members of the commission—Drs. Low, Christy and Castellani—arrived in Uganda on July 10. Drs. Castellani and Low proceeded direct to the Government headquarters at Entebbe, where they arrived on July 12, but Dr. Christy, at the request of the Sub-Commissioner, made a detour in order to proceed by land through Busoga, where the disease is very severe. Dr. Christy arrived at Entebbe on July 27, and intended leaving in a few days for Buddu, on the west shore of the lake. Everything is being done by the authorities to assist the doctors in their investigations, and the Commissioner has ordered the erection of a laboratory at Entebbe. All the scientific apparatus has reached Uganda in good condition. A complete "sleeping sickness" hospital has been prepared, and on July 29 there were ten cases under close study, three *post mortem* examinations having also been obtained. Dr. Castellani had then got all his *media* prepared and the laboratory in order for complete bacteriological examination. Dr. Low has examined the blood of about 600 individuals, with interesting results.

AN International Fishery Exhibition, the first ever held in Austria, was opened on Saturday last in Vienna by the Archduke Franz Ferdinand. The exhibitors are mainly Germans, but France, Italy, Norway and Roumania are represented. England is taking no part in the exhibition.

ACCORDING to the *Athenaeum*, the committee of the fund which was formed in honour of the eightieth birthday of Prof. Virchow has now ended its work, and reports that it has collected 53,652 marks. This, added to the subscriptions to the fund from other sources, will put the Virchow Stiftung in the possession of a sum of nearly 150,000 marks. The yearly interest of the fund was to have been expended on scientific objects specially indicated by Prof. Virchow.

MR. SANTOS DUMONT'S new balloon, the construction of which has been begun, will be 25 metres long by 11 metres in diameter, and will carry two aëronauts and eight passengers.

A REUTER telegram from Budapest states that the electric railway, about 100 kilometres in length, along the shore of Lake Como was opened on September 4. The electrical power, mounting to 20,000 volts, is obtained from the Falls of the Adda. At the stations, the current is reduced to 3000 volts and transmitted through overhead contact wires. The power derived from this source will also be applied shortly to working the motors and electric carriages on the Lecco-Colico line. The new work, which is supplied with a full high-tension electrical system, has been carried out in accordance with the Kando system.

MR. GREGG WILSON has been appointed by the President of the Board of Trade an inspector of fisheries in England and Wales, in succession to Mr. Henry Noel Malan.

A DESPATCH from Carupano, Venezuela, to the *Figaro* states that violent detonations were heard there between ten o'clock on the night of September 3 and four o'clock on the following morning. They came from the north and were identical in character with those which were heard on the night of August 30 during the eruption of Mont Pelée. A message from the St. Thomas correspondent of the *Times*, sent on September 7, states that a slight eruption of the St. Vincent Soufrière took place at noon on September 3, and the inhabitants left Georgetown and Château Belair. At ten o'clock at night there were loud thundering noises and electrical discharges from the volcano, while from one o'clock until four o'clock in the morning there was a continuous roar. Afterwards there were murmurings for two hours. On the morning of September 4 the sky was obscured by dust and smoke, and the scene is described as terrible. Pebbles and dust fell at Barrouallie, and at Château Belair there was a heavy fall of sand. A telegram from Paris on September 7 states that the French Colonial Office has directed M. Lacroix, the head of the scientific mission which was sent to Martinique, to organise the permanent station of operations which is to be established there, and M. Lacroix will start as soon as he has collected the necessary apparatus.

AN earthquake of six seconds' duration was experienced at Pau (Pyrenees) at 2.30 on the morning of September 8.

THE Athens correspondent of the *Times* has called attention to some very destructive forest fires which have recently taken place in Greece, due mainly, it is said, to human agency. In some cases the woods are deliberately set on fire by the peasants for the purpose of making clearances for arable land, or by the shepherds in order to increase the extent of pasturage; in other cases, conflicts between neighbouring communes over the right of cutting timber have led to wanton acts of incendiarism, while lighted matches or cigarettes thrown carelessly into the thickets or sparks from the fires in the shepherds' cantonments are often productive of widespread destruction. As our contemporary remarks, these calamities demand the serious attention of the Greek Government, the loss to the country being very great. Although in recent years the matter has attracted some notice, not much has been done to remedy the evil. True, a society for the reafforestation of the country has been formed, but it is doubtful whether any great success will be attained by voluntary agencies. The matter of the protection of the national forests rests with the Greek Government, which does not appear to be fully alive to the serious condition of things.

THE August issue of the *Elektrochemische Zeitschrift* contains an article by Th. Gross which seems to suggest that silicon is not an element. The author has been investigating the behaviour of silica when exposed to long-continued electrolysis, and in his opinion has proved that some second element is present in the resulting fused mixture. Starting with 15 grams of pure silica, and using 30 grams of pure caustic potash as solvent, an electric current was led through the molten mass for some hours, and the unaltered silica was then removed from the product by the usual chemical methods. The experiment was carried out in a silver crucible. The silica recovered showed a deficiency on the original weight, and the balance was found in 2·8 grams of a substance possessing different physical and chemical properties. This substance was easily soluble in hydrochloric acid. When heated in a porcelain crucible, it melted and yielded a brown mass, which, on treatment with

hydrogen gas, left a grey residue possessing metallic characteristics resembling those of selenium. The experiments, however, require confirmation before the conclusion can be accepted.

THE last number of the *Journal* of the Institution of Electrical Engineers contains chiefly papers read before the various local sections. These show that the policy of the Institution in establishing these sections was a very wise one, the papers being quite equal in merit, if not superior, to those read in London. Mr. Osborne's paper on the lighting and driving of textile mills by electricity, read at Dublin, will be read, we feel sure, with great interest; it shows that the electrical engineer has still a great deal to study with reference to the best kind of light, and its proper distribution, for special purposes. Another paper dealing with a subject of great importance at the present time is that by Mr. Clothier on switch-gears, which is to be specially commended for its very beautiful illustrations. The Institution's *Journal* has shown a very marked improvement in this respect during the past few years; the illustrations published two or three years ago are not to be compared with those which now appear in it.

ACCORDING to the *Scientific American*, the new Marconi Transatlantic signalling station at Cape Breton is nearly completed, and will be ready for commercial working in the course of a few weeks. We reproduce an illustration showing the

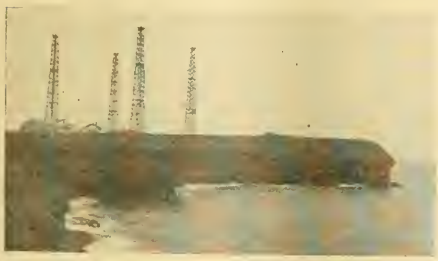

FIG. 1.—The New Marconi Wireless Telegraph Station at Glace Bay, Cape Breton.

general appearance of the station, with its low buildings containing the signalling plant and its four wooden towers for supporting the aerial conductor. These towers are more than 200 feet high (their tops being about 300 feet above sea-level), and are placed at the corners of a 200-foot square. From the top platform of each tower to that of its neighbour is strung a horizontal cable from which the vertical conductors depend; these, 150 in number, are all joined together in the centre of the square, thus forming an inverted pyramid from the apex of which a single cable runs into the apparatus room. The wooden towers are of special design and are well stayed with wire ropes to prevent them from being blown down in a gale. The machinery installed is stated to be more powerful than is necessary for merely signalling to Europe, and hopes are entertained of transmitting messages to Cape Town. As a receiver, the coherer has been discarded and a more trustworthy instrument substituted; this is in all probability the magnetic receiver recently described by Mr. Marconi before the Royal Society.

IN the *Century* for September, Mr. R. T. Hill and Prof. I. C. Russell contribute articles on the West Indian volcanic eruptions, both of which are excellently illustrated with pictures, many of which are published for the first time. Although the text of these articles to a great extent describes observations similar to those with which we are already familiar, here and there, as, for example, in Mr. Hill's description of one of Pelée's eruptions which he witnessed, we find materials well worth the attention of students of volcanic phenomena. Since the articles were written, on the night of August 30, Mont Pelée and the Soufrière in St. Vincent have broken out again, and this time with exceptional intensity. Morne Rouge has disappeared, and there is "not a single creature left to tell the tale." More than a thousand persons are reported to have lost their lives. Carbet was invaded by a sea wave, a portion of the island sinking in the sea; at Fort de France the sea penetrated 40 feet inland, and the water line at that place has risen 5 to 6 feet. These disturbances in the ocean may result from a movement in its bed, which, considering the number of cables which have been interrupted, appears likely, or they may be directly due to the hurricane-like blasts from the mountain. In this last eruption, we again appear to have evidence of a connection between seismic and volcanic activities. The hour at which Mont Pelée and the Soufrière renewed their violence is not known, but on August 30, at 9.59 p.m. (5.54 p.m. St. Vincent's time), an earthquake occurred at a distance of about 62° from the Isle of Wight, which probably disturbed the whole of our globe. If this can be identified with a violent earthquake which at 9 p.m. disturbed Venezuela on that date, we again have a repetition of a history common to all the known West Indian eruptions. The gratuitous prophecies that Martinique is to sink beneath the ocean again appearing in papers are only increasing alarm, depreciating the value of property and giving trouble, not only to the authorities in Martinique, but to the governors in adjacent islands. Although the inhabitants of districts which are threatened are being moved to places of safety, the alarm at the possibility of further devastation is intense. Let this be increased by sensational announcements and there may be panic, the results of which can only intensify calamity.

WE have received from M. Henri Desmarest a copy of his article on "La Houille blanche," which appeared in the *Revue Universelle*. The paper describes in a popular manner the utilisation of water power for industrial purposes, and the author points out that France, having at command a large supply of waterfalls, may hope, by making the most of its advantages, to take a leading place amongst the nations. A table shows that more than 500,000 h.p. is already utilised, but this is only one-twentieth of the power available. The article is copiously illustrated by photographs of waterfalls and turbines, and diagrams showing the general construction of water-power installations; there is also an interesting little map of France, shaded to show the amount of power existing in the different departments. One of the photographs shows the motor erected at Santa Cruz for using the power of the sea waves; this consists of two wells sunk near the sea front, in one of which is a float which is raised and lowered by the waves; the float is connected to, and works, a pump in the second well, which forces the sea-water into a reservoir, from which it can be drawn when required.

A NOTE on the use of Fourier's series in the problem of the transverse vibrations of stretched strings is contributed by Dr. H. S. Carslaw to the current number of the *Proceedings* of the Edinburgh Mathematical Society. Dr. Carslaw proves that where the initial form of the string involves discontinuity in the slope of the curve, the nth term of the series for the displacement is at most of order $1/n^2$, and the series cannot, therefore, be differentiated twice term by term, as would be necessary if the series is to be proved to satisfy the differential equation of vibration. Where, however, no discontinuity occurs in the slope of the string, the nth term of the series is of order $1/n^3$, and the second differentiation term by term is possible. But then, as

Dr. Carslaw remarks, the equation of vibration of a stretched string is obtained on the assumption that no such discontinuities occur; if sharp corners exist, dynamical difficulties are introduced.

THE French Physical Society has undertaken the publication of a collection of elementary physical experiments. This book will describe class experiments, and also simple experiments of a suitable character for class exercises. The first part, dealing with geometry, mechanics, gravity, hydrostatics and heat, is now in preparation.

SOME statistics as to the use of alcohol as an illuminant are given by M. L. Denayrouze in the *Bulletin* of the French Physical Society, No. 185. This use of alcohol, first proposed in Germany a few years ago, has recently been rendered practicable from a commercial point of view by the introduction into France of methylated spirits, and also by an increase in the efficiency of the Denayrouze lamp. Taking 1·08 grams of pure alcohol or 0·64 gram of carburetted alcohol (alcohol carburé) per candle hour as the consumption of this lamp, the cost is estimated at 0·00478 and 0·00298 of a penny per candle hour for these two alcohols, as against 0·01428 of a penny for petroleum. The lamp consists essentially of a wick, conducting the liquid by capillarity into a chamber where it is vaporised, the necessary heat being produced by a copper bar which derives its heat from the lamp itself. The vapour passes through a small channel into a kind of Bunsen burner, above which the mantle is fixed. The series of operations is entirely automatic.

THE *Ceylon Independent* of August 11 contains Prof. Herdman's report on the pearl fisheries in the Gulf of Manaar. The objects of the professor's investigations were fourfold. Firstly, to inspect the oyster banks; secondly, to find out the conditions under which the molluscs live; thirdly, to take into consideration the marine zoology of the other Singalese waters in connection with trawling; and, lastly, to select a spot for a marine laboratory. As the result of the survey, it was found that in the main the oysters were healthy and free from epidemic, and, indeed, from much disease of any description. Parasites were present in considerable numbers, but were not considered to be doing much damage. "Spat" were found in abundance in certain localities, and enormous quantities of young oysters in others. A large percentage of these appeared, however, never to reach maturity, either from being destroyed by enemies, choked in sand or overcrowded. The remedy for this is thinning out and transplanting. It is concluded that "there is no reason for despondency in regard to the future of the pearl-oyster fisheries, if they are treated scientifically."

TWO papers of considerable interest on fossil mammals are to hand. In the one—issued by the Cairo Survey Department—Messrs. Andrews and Beadnell describe remains of new forms from the Eocene of Egypt, among which the lower jaw on which the genus Phiomia is based is perhaps the most interesting and remarkable. The other—published in the *Journal* of the College of Science of Tokio—relates to part of a skull from the Tertiary of Japan believed by its describers, Messrs. Yoshiwara and Iwasaki, to indicate a new type of proboscidean.

IN vol. ii. pt. 10 of the *Annals* of the South African Museum, Sir George Hampson continues his valuable catalogue of the moths of South Africa, describing many new genera and species.

THE Museums Association has issued the first volume of its *Journal*, edited by Mr. E. Howarth, and containing an excellent portrait of Sir William Turner. The volume will be welcome to all interested in museum improvement, whether from the general education standpoint or on more strictly scientific grounds.

THREE memoirs of the Geological Survey of England and Wales have recently been issued in explanation of the one-inch maps. That on Ringwood, by Mr. Clement Reid, is accompanied by a colour-printed map which has been admirably executed by the Ordnance Survey. The area described is a part of the Hampshire Basin, and attention is drawn to the evidence of an old river course, which probably in Newer Pliocene times connected the Salisbury rivers with Southampton, before they were captured and diverted along the course of the subsequent Lower Avon. The geology of Southampton, also by Mr. Reid, with contributions by Mr. Whitaker, gives a concise account of the Chalk and Tertiary strata, and of the Pleistocene deposits some of which yield Palæolithic implements. Several new inliers of London Clay have been recognised, and these indicate an extension to the westward of the Portsdown anticline. The geology of the country around Exeter is by Mr. W. A. E. Ussher, and it gives a fairly full account of the Culm-measures, the various divisions of the New Red Sandstone series, and the superficial deposits. Much interest attaches to the volcanic rocks, which are probably of Permian age, and the field-observations are supplemented by petrological notes by Mr. Teall.

A THIRD report on the soils of Dorset, by Mr. D. A. Gilchrist and Mr. C. M. Luxmoore, has been issued by University College, Reading (1902). Attention is directed to the amount of carbonate of lime in the fine earth of various soils, and it is noteworthy that some soils on calcareous formations contain very little carbonate of lime, while the soil on Kimeridge Clay contains in places more than 2 per cent., an amount which decreases in the subsoil. An interim report is given on the general results of the investigations with regard to West Dorset, and many suggestions are made on the capabilities of the land and on the improvements which might be made in the cultivation of it.

THE *Chemical News* for September 5 is a "Students' Number," and contains much useful information respecting the leading schools of chemistry in the country.

THE additions to the Zoological Society's Gardens during the past week include a Campbell's Monkey (*Cercopithecus campbelli*) from the West Coast of Africa; a Bosman's Potto (*Perodicticus potto*) from West Africa, presented by Mr. G. Robertson; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Dr. Bates; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, a Two-spotted Paradoxure (*Nandinia binotata*), a Dorsal Hyrax (*Hyrax dorsalis*) from the Gold Coast, presented by Mr. A. W. Morris; two Suricates (*Suricata tetradactyla*) from South Africa, presented by Capt. C. F. Wanhill, R.A.M.C.; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Colonel J. S. Ewart; two Naked-footed Owlets (*Athene noctua*) European, presented by Mr. A. J. Challis; fourteen Wall Lizards (*Lacerta muralis*) European, presented by Dr. Lewis H. Gough; two Madras Entellus Monkeys (*Semnopithecus priamus*), new to collection, from Southern India; a Pale Genet (*Genetta senegalensis*) from the White Nile; four Blue Lizards (*Gerrhonotus coeruleus*) from Western North America, deposited.

OUR ASTRONOMICAL COLUMN.

OBSERVATIONS OF VARIABLE STARS OF LONG PERIOD.—Writing in the *Observatory* for September, Prof. Pickering gives an abstract of an earlier paper on the really valuable work that might be done by willing observers who only possess small instruments. He states that the number of telescopes of small size (*i.e.* 10 to 30 cm. aperture) now in use, is out of all proportion to the meagre results obtained by their aid, and suggests that observations of long-period variables by Argelander's method would, if systematically made, prove of real value in furthering our knowledge of these objects.

Prof. Pickering suggests the use of the charts of the Bonn Durchmusterung for this work—and their recent republication renders them accessible to all—but he adds that the star images are too small to use at the telescope; in order to overcome this difficulty, photographic enlargements, on a scale $1' = 0{\cdot}1$ cm., of the regions for 3° around sixty-nine of these variables, have been prepared, and will be forwarded free of cost to experienced observers who are willing to cooperate in this work (*Circular* No. 53, H.C.O.).

To render these observations really valuable, they must be made systematically and each object must be observed once a month, or better still, once a week, by someone amongst the cooperated observers. Then again, the observations must be recorded on a uniform system of magnitudes, and for this purpose it is suggested that the combined observations of the Lick, Yerkes, McCormick and Harvard observatories for the past twenty-five years should be used. When finally reduced and brought together, it is expected that these will embrace all stars, down to the sixteenth or seventeeth magnitude, for the whole of the sky. To facilitate matters further, the whole of the magnitudes on Hagen's charts are being reduced to the photometric scale, so that all that will then be necessary will be to select a star slightly fainter and one slightly brighter than the variable, and record the catalogue numbers, with the date. Further improvement may be made in the observations if the magnitude intervals, and the minute and second of the observation, are also recorded, although the latter are not essential in the cases of long-period variables. Prof. Pickering concludes with the assurance that "if such observations, for which no apparatus but an ordinary telescope is required, are made systematically, results of great value will be obtained."

The Lick Photographs.—In *Bulletin* No. 20 of the Lick Observatory, Prof. Pickering announces that, as so many legitimate requests have been made for the Lick photographs of the moon, comets, nebulæ, &c., it will be possible in the future to purchase lantern slides, copies and prints of these objects on application to the director of the Lick Observatory. The prices and details of these objects may be obtained by teachers, lecturers, &c., on application.

The Dark Spot on Jupiter.—In a letter to the *Observatory*, Herr Leo Brenner refutes the idea that the dark spot which Messrs. Phillips and Denning observed in the neighbourhood of the Great Red Spot on June 28, is the same spot that he recorded, and named the "pyramid-spot" during the opposition of 1901. He states that the movement of the pyramid-spot during last year was 48° in 85 days, therefore it is impossible for it to have moved the same distance in eight days this year, as it must have done if it is the same spot that was recorded as being under 19° on June 28.

THE IRON AND STEEL INSTITUTE.

THE autumn meeting of the Iron and Steel Institute was held at Düsseldorf on September 3 and following days, and was attended by an unusually large number of members. Mr. William Whitwell, the president, was in the chair, and he was supported by Sir Lowthian Bell, F.R.S., Sir James Kitson, M.P., Mr. Snelus, F.R.S., Sir J. J. Jenkins, M.P., Mr. J. Walton, M.P., Mr. E. Parkes, M.P., and numerous other prominent members from various parts of the world. Addresses of welcome were delivered by Mr. von Holleuffer, the governor of the Düsseldorf district, on behalf of the Prussian Government, by the Mayor of Düsseldorf on behalf of the city, and by Mr. H. Lueg on behalf of the exhibition authorities and the local reception committee. Nine papers were then dealt with. Mr. W. Brügmann read the first paper, which gave an exhaustive account of the progress in the manufacture of pig iron in Germany since the Institute last met in Düsseldorf in 1880. A similar paper dealing with the progress in the manufacture of steel was read by Mr. R. M. Daelen, and Prof. H. Wedding read a paper on iron and steel at the Dusseldorf exhibition. Prof. Heyn, of Berlin, then read an elaborate paper of great scientific and practical interest on the overheating of mild steel. The principal conclusions drawn from the author's researches were as follows:—

When low-carbon mild steel is annealed at temperatures above 1000° C., there is an increase in the degree of brittleness if the annealing period is sufficiently long. This increase is more considerable, and manifests itself the sooner, the higher the temperature of annealing.

Prolonged annealing, say uninterrupted for fourteen days, at temperatures between 700° and 890°, produces no increase in the brittleness. In such cases where the brittleness of the material in its initial state was not yet at the lowest degree possible, by this treatment the lowest degree of brittleness will be attained. Between 1100° and 900° there exists a temperature limit, above which, if annealing is carried on for a longer period and at an increasing temperature, the degree of brittleness increases. Below this limit, however, this is not the case. Overheating does not only occur at most extreme white heat, but manifests itself at considerably lower temperatures, which must, however, exceed the temperature limit just referred to. By suitable annealing, the brittleness of overheated low-carbon mild steel can be eliminated. If annealing is carried out at above 900° C., a short period of about half-an-hour is sufficient. Longer annealing must be the more carefully avoided, the more the temperature limit between 1100° and 900° is exceeded, otherwise the signs of overheating reappear. Below 800° an annealing of even five hours is not sufficient to eliminate the brittleness in overheated low-carbon mild steel, but by annealing of several days' duration, at temperatures between 700° and 850°, this object can be attained. If low-carbon mild steel, which has been annealed for a longer period at a high enough temperature, so that after undisturbed cooling it would show extreme brittleness, is rolled or forged during cooling to bright red-heat, it will exhibit no brittleness when cold. The fracture of overheated low-carbon mild steel generally shows a coarse grain, although this is not necessarily always the case. The single crystal grains of which the structure of the iron is built up, which can be detected under the microscope by suitable etching, are often of considerable dimensions when in the state of overheating. Nevertheless, this is not to be considered as proof positive that overheating has taken place, since the method of cooling also exercises a great influence on the size of the ferrite grains. Rapid cooling from the temperature causing overheating produces fine ferrite grains, without reducing the brittleness appreciably. Moreover, it is possible, by heating low-carbon mild steel for days together at between 700° and 890° C., to bring the material into such a condition that it will show exceedingly coarse ferrite grains, and yet not exhibit brittleness.

An interesting discussion followed the reading of this paper. Mr. J. E. Stead took exception to some of the conclusions. Prof. Tschernoff, of St. Petersburg, described his early researches on the same subject. Mr. Saniter and Mr. Lange supported Mr. Stead.

The first paper dealt with on September 4 was on the compression of steel during solidification in the ingot mould, by Mr. A. Harmet, of Saint-Etienne. This paper, which covers 64 pages, was read in abstract by the secretary, Mr. Bennett H. Brough. Compression with a static pressure acting on the top of the ingot is the principle involved in the Whitworth process. In the Harmet process the upper portion of the ingot is left exposed, and pressure is applied to the base, causing the steel to rise in the conical mould as though being forced through a draw-plate. The process has been introduced with great success and economy at the Saint-Etienne steelworks. In the discussion, favourable opinions of the invention were expressed by Mr. Beardmore, Mr. Windsor Richards, Mr. Snelus, Prof. Howe, of New York, Mr. Vaughan Hughes, Mr. Saniter and Prof. Tschernoff.

Mr. D. Selby-Bigge next read a paper on the application of electric power in the iron and steel industries, and Mr. F. Kylberg, of Benrath, near Düsseldorf, read a paper describing some developments of the use of electricity in ironworks based on American experience and adapted to European requirements. An interesting discussion followed in which Sir Lowthian Bell, Mr. W. H. Massey and several leading continental electrical engineers took part.

Prof. E. D. Campbell and Mr. M. B. Kennedy, of the University of Michigan, communicated a paper on the probable existence of a new carbide of iron, Fe_3C; and Mr. L. F. Gjers and Mr. J. H. Harrison gave a report of the results obtained in equalising the temperature of hot blast. The proceedings concluded with the usual votes of thanks to the local reception committee and to its hon. secretary, Mr. E. Schrödter, who had planned a most attractive programme of visits and excursions. The works visited included the Krupp establishment at Essen, the Union, Hoerde and Hoesch steelworks at Dortmund, the Phœnix works and the Rheinische Stahlwerke at Ruhrort, the

Gutehoffnungshütte at Oberhausen, and the Vulcan steelworks at Duisburg. In each case the members were received with great cordiality and with lavish hospitality. Visits to the exhibition under expert guidance were also organised, and numerous works in Düsseldorf were thrown open to members. The social functions in connection with the meeting included a conversazione given by the Mayor and Corporation on September 3, a banquet on September 4, at which seven hundred ladies and gentlemen were present, a firework display in honour of the Institute at the exhibition on September 5, and an excursion on September 6 to the Kaiser bridge at Müngsten and to the hanging railway at Elberfeld. For the ladies accompanying the members a programme of excursions was organised by a committee of Düsseldorf ladies. At the conclusion of the meeting there were supplementary excursions to the Peine and Ilsede ironworks, and to the steelworks near Saarbrücken and Luxemburg. Altogether the meeting was one of the most attractive and successful recorded in the history of the Institute. It was announced that the next president of the Institute will be Mr. Andrew Carnegie, vice-president, who will come into office in May next.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ATTENTION has already been directed in these columns (vol. lxv. No. 1679, p. 216) to the statistics collected by the council of the Association of Technical Institutions comparing the number of day students of fifteen years of age and upwards who are taking complete day technological courses of not less than twenty hours a week in Great Britain and Ireland, with the number of students of a similar kind in the German technical high schools. The German Ambassador has since supplied the council of the Association of Technical Institutions with additional statistics in regard to technical high schools in the German Empire. The conditions of entry to the German schools are such that they very rarely contain any students under eighteen years of age. The additional information now available shows that the number of matriculated students in German technical high schools, of the age and status described, in each of the following branches of technology is:—Agriculture, 42; architecture, 1440; civil engineering, 2257; mechanical and electrical engineering, 5503; naval architecture and marine engineering, 318; chemistry and metallurgy, 1180; general knowledge, 280; and forestry, 12. These numbers do not include 1390 students in the above subjects attending institutions at Brunswick and Stuttgart. The figures give a total of 12,422 students, and if in addition non-matriculated students are counted, the total reaches 15,442. It is especially noteworthy that 935 of the matriculated students enumerated have each attended for more than four years. When referring to this subject on the previous occasion, it was pointed out that the total number of students in Great Britain and Ireland above fifteen years of age taking complete day technological courses of not less than twenty hours a week is 3873, and only 113 of these have attended more than three full years.

WE have received a syllabus of the courses on electrochemistry and electrometallurgy to be held at Owens College, Manchester, during the coming session. In addition to the general theoretical and practical courses, Mr. R. S. Hutton will give a series of six lectures on electrometallurgy on Saturday afternoons, and also a special electrochemical course on Monday evenings. The electrochemical laboratory, which is part of the new physical laboratories opened two years ago, is very well equipped with power and apparatus for all kinds of electrochemical and electrometallurgical work, possessing two 600-ampere furnaces of the Moissan type. Probably no other technical college in the country can boast of such facilities, and Manchester is to be congratulated on moving with the times and making adequate provision for the study of a much-neglected but highly important branch of science.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 19.—"On Two Methods for the Limitation and Regulation of Chloroform when administered as an Anæsthetic." By A. Vernon Harcourt, M.A.

"The Seed-fungus of *Lolium temulentum*, L., the Darnel." By E. M. Freeman, M.S.

PARIS.

Academy of Sciences, September 1.—M. Bouquet de la Grye in the chair.—On the eruption of Martinique, by MM. A. Lacroix, Rollet de l'Isle and Giraud. A short summary of the results obtained by the commission sent out by the Academy to study the effects of the eruption. A single measurement of the height of Mont Pelée showed that its height had not appreciably changed, so that the summit of the mountain has not been completely blown away, as was at first conjectured. No new crater appears to have been formed, although numerous fissures have opened. Volcanic eruptions are usually characterised by two classes of phenomena, the explosive evolution of gases with solid or fused siliceous materials, carried to a very high temperature, and the outflow of similar fused siliceous materials in mass. The present eruption is characterised by the total absence of this latter phenomenon, the so-called lava streams described by eye-witnesses consisting in reality of torrents of boiling mud, with large masses of moving rock. No actual flames have been observed by the members of the commission, the only certain fact about the constitution of the gases evolved being the presence of steam and sulphur dioxide, the latter being in great abundance as indicated by its suffocating odour. Fumerolles are very abundant, and it is owing to the presence of these that the rivers undergo violent fluctuations of temperature. Observations were also made of the topographical changes, variations in the depth of the sea near the coast line, together with electrical, magnetic and meteorological observations.—On entire and quasi-entire functions and differential equations, by M. Edmond Maillet.—On differential equations of the second order with fixed critical points, by M. R. Liouville.—The electrolysis of mixtures of salts, by M. Anatole Leduc. The presence of metallic impurities such as are likely to be present in commercial silver has no practical effect upon the electrochemical equivalent of silver.—The classification of binary accords. Specific consonances and dissonances, by M. A. Guillemin.—The action of soluble ferments and of high yeast upon gentiobiose. Remarks on the constitution of gentiobiose, by MM. Ed. Bourquelot and H. Hérissey.—On the proteolytic action of snake venom, by M. L. Launoy.—On the difficulty of isolating the *Bacterium coli* in colonial dysentery, by M. Lesage.—The preventive treatment of scab, and on the use of an anti-scab serum, by M. F. J. Bosc. The physical, chemical and practical results of the concentration of wine, by M. F. Garrigou.

PROF. LORENTZ ON THE SCOPE OF PHYSICS.

Sichtbare und Unsichtbare Bewegungen. Vorträge gehalten von H. A. Lorentz. German Translation by G. Siebert. Pp. 123. (Brunswick: Vieweg und Sohn, 1902.) Price Mk. 3.

THESE lectures, published under the title of "Motions Visible and Invisible," were delivered at Leyden last year to what would, perhaps, be called in this country a philosophical society. The object was to present to a general audience an outline of the picture of the external world which modern physics is constructing within its own province, without going so far into detail as to lose the general outlook in the interests or difficulties of special departments of knowledge. The keynote of the book, as the title implies, is that all physical explanation rests ultimately on dynamics; and accordingly the first three out of seven lectures are devoted to an exposition of the gist of the dynamics of rectilinear, curved and vibratory motions. Not much originality is to be expected in such well-worn topics, but the freshness of some of the illustrations reveals the calibre of the author. Such, for instance, is the estimation, from Hertz's analytical theory, of the intensity of the pressures set up in the ordinary impact of small balls; when a ball of 800 grammes falls on another such from a height of 12 cm., the total pressure between them mounts up to the order of 600 kilogrammes. The results developed are applied to a brief review of the cardinal phenomena of sound and light, and to the explanation of gaseous pressure and temperature on the kinetic theory. Of personal interest is the remark, on the basis of Michelson's having found that the breadth of a spectral line of a gas approaches a definite limit as the gas is rarefied, that, according to the writer's belief, we have here as direct evidence for the motion of the gas-molecules as spectral displacements give for the motions of the heavenly bodies. We naturally turn to the sixth lecture, on electrical phenomena, in the elucidation of which the author occupies so prominent a position. At the very beginning, the conception is introduced that the ultimate atoms of matter involve positive and negative electrons, which interact through the connection between them that is afforded by the æther, and thus originate all electric phenomena. In the terms of this theory, the main electric phenomena are described, including such as kathode rays, though not much attempt is made to indicate the links of the chain of deduction that bind together the various departments of electrodynamics; finally, a rather more detailed sketch of the significance of the Zeeman effect is given. Thus one is led to see how it comes about that it is now a main effort of physicists to ascribe to these electrons a function in many types of phenomena, and to realise that there is much evidence for the view that they form a very prominent element in the constitution of matter. So far as is known, they are the sole links between ponderable matter and the æther. On them, too, a hope entertained by many is largely based, that gravitation and molecular forces will also turn out e processes in that medium. The last lecture is an exposition of the principle of energy. The writer expresses his opinion that nothing short of careful experimental investigation can assure us of the impossibility of the *perpetuum mobile*, which forms the foundation of the doctrine of energy. The ramifications of that principle are illustrated from the action of a dynamo. The principle thus forms a clue that connects the most varied phenomena, even when we are ignorant of the mechanisms which produce them; we find it an unfailing guide in tracing relations, with a certainty to which no electron-theory or other special theory can pretend. But it is of limited scope; the independence *e.g.* of gaseous viscosity and density, or the effect of motion on spectra, can only be elucidated by penetrating beneath the surface of things and resolving the phenomena into their elements.

To some people, the other side of the question above referred to as to the nature of the negation of the *perpetuum mobile* will doubtless appeal more strongly. A fundamental principle in nature of simple and universal type can hardly be based exclusively on the empirical ground of experimental verification; indeed, this very principle is constantly being applied without any hesitation to considerations so delicate as to be beyond the reach of present experimental confirmation except as regards their remote results. Not the least interesting and promising topic in abstract physical science is the origin and scope of the great natural laws which transcend all distinctions between different kinds of material, and form the frame into which the science is gradually built.

The sketch here given will show that Prof. Lorentz's little book forms a welcome addition to the expositions, popular yet exact, which we possess of the current progress of physical science, even in this country which produces more than its share of such concrete and illustrative presentations; all the more so as the trend of scientific method abroad now seems to seek greater security in the purely abstract exposition of relations, between entities which appear only as pure unknowns by means of mathematical symbols, from the fear that any full-bodied analogy traced between them and other things better known may, by reason of its limitations, encourage views that may ultimately prove false.

J. L.

CELTIC MYTHOLOGY.

Cuchulain of Muirthemne: the Story of the Men of the Red Branch of Ulster. Arranged and put into English by Lady Gregory. With a Preface by W. B. Yeats. Pp. xvii + 360. (London: John Murray, 1902.) Price 6*s*.

EVEN before the appearance of this attractive volume the general reader had no valid excuse for not knowing something of the story of Cuchulain and the other heroes of Ulster; henceforward he will be still more inexcusable if he persists in ignorance. No one who cares at all for early literatures can fail to enjoy this version of these old Irish tales, so unique of their kind and so full of varied interest. The serious student, no doubt, will prefer to go direct to the originals, or to close translations like those collected in Miss Hull's "Cuchullin Saga"; but Lady Gregory's work is so different in aim from Miss Hull's that there is ample room for both. She

has been chiefly attracted to the tales by their literary merits, and has sought with no little success to make these the prominent feature in her renderings. This at times involves the omission of details that are not without interest, but, after all, there is enough left to give a fair impression of what can be learned from the old literature of Ireland. This mass of legend, for the most part taking its final form about the twelfth century, but demonstrably far older in origin, is, in fact, a perfect mine of primitive custom and belief, and as such is full of interest for the anthropologist. Where the ordinary reader will only see something fanciful or unintelligible, the specialist will often discern an interesting survival or a striking parallel, even if it is hard at times to draw the line between Irish tradition and Irish imagination.

The peculiar character of these tales is due to a double tendency in Irish literature. On the one hand there is an exuberant imagination which recklessly transcends all limits of time and space ; on the other there is a love of minute detail which constantly brings in the smallest features of everyday life and work. To the latter tendency we owe the minute descriptions of the appearance and dress of the heroes, of their horses and chariots, their arms and modes of fighting, their palaces and forts, and so on. It is a kind of Homeric life and culture that meets us here, yet with a greater admixture of primitive types, civilisation and barbarism being strangely intermingled. Nor does the Homeric Olympus lack its counterpart, for behind the real world of mortal heroes lies the realm of the Sidhe and the Tuatha De Danann, constantly reminiscent of the old Celtic mythology which Christianity has displaced. With a real and an imaginary world to move between, there is nothing that the Irish story teller will not dare to say ; nothing is either too mean or too marvellous for him. Man and animal are interchangeable beings. Cuchulain himself is a reincarnation of Lugh (one of the old gods), who takes the shape of an insect and is swallowed by the sister of Conchubar. Curói makes his fort whirl round like a millstone all night, so that no one can enter it after sunset. The bridge in Scotland which Cuchulain has to cross can alter its own shape and size at pleasure. Conchubar's shield moans when he is in danger, "and all the shields of Ulster would moan in answer to it." Wells and streams have a faculty of bursting out and overflowing whole tracts of country, and it is out of two lakes that Cuchulain gets his famous pair of horses, the Grey and the Black. Charms and spells are as potent as in Africa, and satire may be so deadly as to kill its victim. Fingan the physician "could tell what a person's sickness was by looking at the smoke of the house he was in." It is three champions of the Sidhe who have to be killed three times before they are done with ; but even mortal heroes have an almost feline tenacity of life. It is well for them that this is so, for their chief happiness consists in fighting ; in cases of single combat the chariot-driver usually looks on and encourages his master, or goads him on to do his best by means of bitter taunts. Feats of strength and skill are naturally common, but some of those mentioned are not easy to understand. Still stranger are the distortions of Cuchulain when in a rage, for which Lady Gregory has substituted the very euphemistic statement that he assumed the appearance of a god ; the direct opposite would not overstate the case. Contention and jealousy are rampant among the heroes, and each unblushingly sounds his own praises and states his claims to the "Champion's Portion," which after all is only a certain quantity of food and drink. Yet the spirit of chivalry is not wanting, and an adventurous quest is greatly to their minds. But while they are ready to face most dangers without shrinking, the power of *geasa* or taboo lies heavy on them. Before Conaire meets his death, he has succeeded in doing everything which he ought not to have done. Historically these *geasa* are known from the "Book of Rights," and form a curious study. Of great interest, too, is the periodic weakness of the men of Ulster, which has been the subject of much discussion among scholars.

As to the central figures in the cycle, Conchubar and Cuchulain, many difficult problems present themselves. It is possible that they take the place of older mythological personages, especially as Conchubar is actually called a god in one text and Cuchulain is the representative of Lugh. Those who are interested in this feature of early Irish literature may be referred to Prof. Rhys's Hibbert lectures, where the solar explanation of Celtic myths receives full consideration, and to Mr. Nutt's study of the "Celtic Doctrine of Rebirth" in "The Voyage of Bran." It is precisely because these Irish tales can provide materials for serious works of this kind that their perusal will be found, not only interesting, but profitable ; and this new version of the Cuchulain cycle may do good service in spreading a knowledge of Celtic legend outside the small circle of scholars who have made it a subject of special study.

OUR BOOK SHELF.

Flora Arctica. Part i. By C. H. Ostenfeld. Pp. xi + 136. (Copenhagen : Det Nordiske Forlag, 1902.)

THE records of plants collected in the Arctic regions are for the most part scattered through numerous papers and written in various languages. At the request of Prof. Warming, Mr. O. Gelert in 1898 undertook to work up, revise and combine the accumulated data, basing his investigations on the collections belonging to the Copenhagen Museum. The work promised to be so extensive that he requested Mr. C. H. Ostenfeld to cooperate with him. This cooperation was cut short in 1899 by Mr. Gelert's premature death, and since that time Mr. Ostenfeld has continued the work alone. The limits of the Arctic territory as here interpreted coincide fairly nearly with the limits of the wood-boundary. This has its anomalies, for, as shown by the map provided, all Greenland is included almost to the 60th parallel, while Iceland in longitude 65° N. and Norway which extends higher than the 70th parallel are excluded. This the first volume contains the Pteridophyta, Gymnospermæ and Monocotyledons. The Pteridophytes are very few in number, the large group of Filices being limited to ten species. The Gymnosperms included are but three, this being the result of the boundary adopted. Amongst the Monocotyledons the most extensive orders are the Gramineæ, with twenty-four genera and sixty-one species, and the Cyperaceæ, including six genera, of which Carex, the most important, is subdivided into fifty-four species. In dealing with this genus the author has had the benefit of Mr. C. B. Clarke's valuable assistance. The Gramineæ were undertaken by Mr. Gelert, and the arrangement given is that left by him. The larger proportion of the illustrations refer to the Carices ;

the figures of the general appearance are good, but the sketches of details, as, for instance, the utricles, are too small to help much in determination of species. They would be more satisfactory if they were drawn natural size or larger. The book is written in English.

An Arithmetic for Schools. By J. P. Kirkman, M.A., and A. E. Field, M.A. Pp. lxvi + 492. (London: Edward Arnold, n.d.) Price 3*s.* 6*d.*

THE distinguishing characteristics of this book are simplicity and great clearness of exposition. The first two chapters deal mainly with our terrible English system of weights and measures, and in this lawless region no skill on the part of an author can be of service to the beginner. Once this tangled wilderness is passed, however, the skill of the authors in exposition comes into play. The treatment of common measures and multiples and the various rules for ascertaining rapidly whether a given number is or is not divisible by specified numbers are very clearly and successfully explained. The philosophy of the rules for the division and multiplication of vulgar fractions is very plainly set forth, and the rules for the contracted multiplication and division of decimals are well explained and illustrated near the end of the book. We have also an account of the metric system, followed by numerous examples of "practice." After this we have the calculation of areas and volumes, and an adequate exposition of the method of extracting square and cube roots. This is followed by the treatment of interest, stocks, and the various branches of the subject which are found in all arithmetical treatises, and then comes an enormous collection of examples. An appendix explaining and illustrating the use of squared paper for the comparison of scales and other kinds of calculation forms a useful and interesting conclusion.

The work is one which can be very confidently recommended to all teachers and students of arithmetic.

A First Step in Arithmetic. By J. G. Bradshaw, B.A. Pp. vi + 166. (London: Macmillan and Co., Ltd., 1902.) Price 2*s.*

ONLY the first four rules, simple and compound, are covered by this book, but the exercises upon them have been so carefully selected and arranged that children who receive instruction through them will acquire an intelligent and working knowledge of simple arithmetic. The exercises are arranged for both oral and paper work, and there is no doubt that the combination of the two methods of teaching the subject gives the best educational result. In most text-books of arithmetic, the pupils are discouraged at the outset by exercises and problems beyond their comprehension, but Mr. Bradshaw deals with amounts which beginners will have no difficulty in grasping and will work out successfully. An essay containing hints on methods of presenting the early rules of arithmetic, which occupies the first twenty-nine pages, contains some notes of service to inexperienced teachers of children; but they are out of place in a pupil's book, and belong rather to a volume on the practice of teaching.

The Real Origin of Religion. By Jabelon. Pp. 48. (London: Simpkin, Marshall and Co., Ltd., 1902.)

THE object of this pamphlet is to establish the not very novel or fortunate hypothesis of the phallic origin of all religious symbolism. The proofs offered are of three kinds, none of which possesses any real cogency. Certain savage tribes attach great importance to circumcision and other mutilations of the sexual organs, the reason for which is unknown. Therefore, the author argues, *all* primitive ceremonialism must be of sexual significance. This conclusion is supported by a number of etymologies, all unscientific and demonstrably false, and by an obscurely worded attempt to interpret the vision of Ezekiel as an account of the anatomical structure of the brain. The scientific value of the farrago is precisely *nil.*

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Re Vegetable Electricity.

I AM reluctantly obliged to traverse a statement made by Prof. J. C. Bose (in the *Journal* of the Linnean Society of July 21, p. 304, footnote) to the effect that "Dr. Waller has subsequently been able to confirm the results which he (Dr. W.) heard me describe on the occasions referred to (Royal Institution, May 10, 1901; Royal Society, June 6, 1901).

I am compelled to state that Prof. Bose, previously to these dates, visited my laboratory on several occasions, received every facility that I was able to afford him as regards the methods by which I was and am investigating the physiological properties of animal and vegetable protoplasm, and *inter alia* heard from me, and has doubtless forgotten, the statement that the electrical response of plants is a general property of vegetable protoplasm, and not confined to such plants (dionæa, mimosa, &c.) as exhibit obvious movements.

Prof. Bose obtained (with my full approval) from my laboratory-mechanic the principal instruments used by me in such investigations, has imitated some of my experiments, and has gradually adopted their guiding theory. He is not entitled to make the statement quoted above.

AUGUSTUS D. WALLER.

P.S.—In connection with this subject of vegetable electricity I may take this opportunity of commenting upon two series of observations that have been made in Germany in contradiction of some of my principal conclusions.

Prof. Adami, of Hof, quotes from the German translation of 1899 of my "Lectures on Animal Electricity," published in 1898, the following passage:—"Verbindet man zwei Punkte A und B der unverletzten Kartoffel mit dem Galvanometer, so lässt sich kein merklicher Strom nachweisen; sobald aber die Kartoffel an einem Punkte B durch einen Messerschnitt verletzt wird, schlägt der Lichtfleck nach rechts aus, infolge der chemischen Thätigkeit und elektromotorischen Kraft, die durch den Schnitt erregt worden sind. Man beachte, dass dieser Versuch, im strengsten Sinne des Wortes, eine Vivisektion ist. Fur unseren Zweck muss die Kartoffel lebendig sein. Die Wirkung bleibt vollstandig aus, wenn die Kartoffel durch kochen getotet worden ist."[1]

He then proceeds to give an account of a considerable number of experiments contradictory of the above statement. Prof. Adami, of Hof, did not use unpolarisable electrodes, but copper pins. It is not surprising that he should have failed to observe any signs of vegetable electricity.

Dr. Arthur Tompa, working in the Botanical and Physiological Institutes of the University of Halle, under the direction of Prof. Bernstein and Prof. Klebs, and with the advantage of the knowledge and experience of Dr. Tschermak, quotes on p. 100[2] the ten headings of my communication at the Turin Congress on Vegetable Electricity, and quite correctly selects for reinvestigation as being the general and most important topic, paragraph 5, "The Electrical Response as a Measure of 'Vitality.'" He devotes much time and care to this reinvestigation, and somewhat reluctantly comes to the conclusion that Waller's blaze reaction is a fallacy arising from the fact that Waller has followed erroneously the direction of current. He devotes a diagram and a page of description, p. 104,[3] to his hypothesis in explanation of this imaginary blunder. I do not think that I have mistaken the direction of current, or that Dr. Tompa could have supposed that I was liable to do this if he had been at the pains to look at any of the diagrams in any of the papers of mine that he quotes.

Dr. Tompa should also have noticed in any of these papers that I have always spoken of excitation by induction currents and by condenser discharges. He has used the direct current of one or more Daniell cells. I have never done this for the reason that such currents give predominant polarisation counter-currents on living and on dead tissues alike. The blaze

[1] Sonderabdruck aus dem ii. *Bericht* des nordoberfrankischen Vereins für Natur-Geschichts- und Landeskunde.
[2] A. Tompa, *Beiträge zur Pflanzlichen Elektricität* ("Botanisch. Beiheften," original arbeiten).
[3] *Idem Ibid.*

reaction, whether unequivocal (homodrome) or equivocal (antidrome) requires short strong currents for its manifestation. I have therefore always used induction shocks and condenser discharges, as stated even in the extremely brief Turin abstract quoted by Dr. Tompa.

I shall be surprised if Dr. Tompa does not repeat the experiments, and from the courteous tone of his account of the matter I think it probable that he will withdraw his stricture on my work when he has witnessed for himself the clear and indubitable results of the experiments.

Can Carbon Dioxide be "Vitalised"?

THERE has long been present in my mind an idea to which I have hitherto hardly dared give expression. The query forming the above heading amounts to the raising of the question whether the carbon dioxide which is exhaled as a product of animal or vegetable vital processes differs in any way from the carbon dioxide of "inorganic" origin formed, let us say, from carbon by combustion in oxygen. The answer will probably be in the negative, since, on theoretical (stereochemical) grounds, an asymmetric structure is not possible in the case of this molecule. Nevertheless, it might be worth while to cross-examine nature on this point. It is, in fact, possible that the experiment may have been already tried with negative results, and that is why I venture into print, since I have been unable to find any record. Two ways occur to me for submitting the question to the test of experiment. Calling the carbon dioxide from the two sources "inorganic" and "organic" respectively for the sake of brevity, the "organic" gas might be obtained either from the brewer's vat or from a carbonate formed from the carbon dioxide of animal respiration. The rate of absorption of this gas might be carefully compared with the rate of absorption of a specimen of "inorganic" gas by a growing plant. This is a method which appeals to vegetable physiologists. The other method, which is more purely chemical, depends upon our being able to obtain some optically active compound sufficiently basic to absorb carbon dioxide. I cannot call to mind any such compound at the present moment, and from where I am writing I have no access to the usual sources of information. Given, however, an optically active base capable of forming a carbonate, would the gases from the two sources be absorbed at equal rates? Perhaps some of your readers may be able to dispose of these queries offhand. R. MELDOLA.

Easton Park Cottage, Dunmow, September 13.

Effect of a Lightning Flash.

DURING the storm on Wednesday, September 10, a house opposite my rooms in Fulham was struck by lightning at 4.40 p.m. Curiously enough, at the moment of the occurrence I was looking at the exact spot, and it may be of interest to record what occurred. A stack of brickwork about ten feet high capped with two red-pot chimneys about three feet high was struck, and a hole was made in the slates of the roof on the south side of the stack. One chimney was shattered. The flash was extremely brilliant and left a perfectly straight line of light on the retina; the length of the flash appeared to be twenty feet, but its upper part was lost in the diffused daylight. The flash was of several seconds' duration and was followed by a thin column of smoke; both these facts are due in my opinion to the fusion of the soot in the chimney. The flash itself was a mere line, otherwise the appearance of the whole strongly reminded me of a cordite discharge from a big gun. There was a loud report, and the circumstances left little doubt in my mind that the electrical discharge was upwards in direction.

C. DAVIES SHERBORN.

Bipedal Locomotion of a Ceylonese Lizard.

I HAVE frequently observed with interest the erect attitude assumed by the small Agamid lizard *Otocryptis bivittata*, Wiegm., when running rapidly, and have long suspected that the short front legs were not used at such times. But the rapidity with which the animal runs, and the nature of the ground which it usually frequents, have prevented very close observation. I have, however, recently fully satisfied myself that its action is truly bipedal. The lizard happens to be common in the Botanic Gardens here, and on several occasions one of them has crossed a smooth sanded road immediately in front of me. I have thus been able to see clearly that the anterior limbs are carried quite free from the ground, progress being effected solely by the long hind limbs.

It seems possible that the closely allied and similarly built lizard *Sitana ponticeriana*, Cuv., may have the same habit. Does the Indian species of Otocryptis (*O. beddomii*) progress in the same fashion?

At present the habit has been recorded only of one or more Australian lizards, notably the "frilled lizard" (*Chlamydosaurus kingi*), which has been very cleverly photographed in the erect attitude by Mr. Saville Kent. E. ERNEST GREEN.

Peradeniya, Ceylon, August.

A Series Related to Bernoulli's Numbers.

THE following seems to be a useful and interesting series :-

$$\frac{r}{r+1} = \frac{D_1}{r+1} + \frac{D_2}{|\underline{2}} + \frac{rD_3}{|\underline{3}} + \frac{r(r-1)D_4}{|\underline{4}}$$

$$+ \ldots\ldots\ldots\ldots$$

$$+ \frac{r(r-1)\ \ldots\ (r-p+3)D_p}{|\underline{p}} + \ \ldots$$

$$+ \frac{r(r-1)D_{r-2}}{|\underline{4}} + \frac{rD_{r-1}}{|\underline{3}} + \frac{D_r}{|\underline{2}},$$

where

$$D_r = 1\,;$$
$$D_{r-1} = \tfrac{1}{2} = 3B_1\,;$$
$$D_{r-3} = -\tfrac{1}{6} = 5B_2\,;$$
$$D_{r-5} = \tfrac{1}{6} = 7B_3\,;\ \&c.,$$

and generally for all odd values of $p > 1$,

$$D_{r-p} = -\left\{(-1)^{\frac{p+1}{2}}\right\}(p+2)B_{\frac{p+1}{2}},$$

$B_1, B_2, \ldots$ being the numbers of Bernoulli.
Also

$$D_{r-2} = D_{r-4} = D_{r-6} = \ \ldots\ = 0.$$

I have been trying since last year, without success, to ascertain whether this is a known series previously published. If it is, perhaps some of your readers will be good enough to supply a reference. J. R. SUTTON.

Kenilworth, Kimberley, August 7.

FREDERICK AUGUSTUS ABEL.

THE death of Sir Frederick Abel on Saturday, September 6, at the age of seventy-five, removes a conspicuous figure from the world of science and technology and brings to a close a long and useful public career. For some years he had been in failing health, but his sudden death, which came painlessly from cardiac failure following one of those attacks of shivering and rigor to which he had long been subject, was quite unexpected.

Frederick Augustus Abel was born in 1827, being the son of Mr. J. L. Abel, of Woolwich. The family, which appears to have been of Swedish origin, had already produced men notable in science, music and painting. Abel has given in the Hofmann memorial lecture, which he delivered to the Chemical Society in 1893, an amusing account of his unsuccessful attempts in the early 'forties to learn chemistry at the Polytechnic Institution of those days; and these recollections perhaps impelled him in the efforts he subsequently made to improve the quality of technical education in this country. In 1845, he entered the Royal College of Chemistry as one of Hofmann's first pupils, and was soon promoted to be an assistant, which he remained until 1851, when he was appointed professor of chemistry at the Royal Military Academy at Woolwich, succeeding Faraday in this position. In 1854, he became chemist to the War Office, a post which he held until 1888, when he retired under the regulations of the Civil Service. It was during this period of thirty-four years that he made his

most important contributions to chemistry in its applications to explosives and to metallurgy. Foremost among these are his researches into the preparation and uses of gun-cotton as an explosive, which were summarised in a paper printed in the *Philosophical Transactions* of 1866 and in the Bakerian lecture which appeared in the *Philosophical Transactions* of the following year. Gun-cotton was already known at that time, but it was generally regarded, at any rate in this country, as a dangerous and probably inefficient substitute for gunpowder. Abel showed, as the result of a long series of carefully chosen and elaborate experiments, how the material may be safely prepared of constant composition, how it should be stored, and also indicated its value as an explosive agent. These papers are eminently characteristic of the practical bent of Abel's mind. Though interested in the progress of pure science, his own inclinations were in the direction of its applications. With the exception of a few of his early papers, written whilst he was Hofmann's assistant, nearly all his contributions have been to the applications of chemical science, and have been made with the express purpose of solving practical problems.

In connection with his other work on explosives, the researches, carried on in conjunction with Sir Andrew Noble, on the chemical changes resulting from firing gunpowder under various conditions and those on the detonation of explosives may be specially mentioned. In 1888, Abel was appointed chairman of the Government Committee on Explosives, and as a result of a series of experiments conducted under its auspices, the smokeless explosive known as "cordite," containing both guncotton and nitroglycerine, was patented by Abel and Dewar, and became the standard explosive of this country.

The influence of composition on the properties of steel and its analysis and the testing of petroleum also engaged his attention. The apparatus known by his name which he devised in connection with the Petroleum Acts of 1868 and 1879 for determining the temperature at which petroleum gives off inflammable vapour is still in general use, and he became a recognised authority on petroleum and its employment as an illuminating agent.

As a member of the Royal Commission on Accidents in Mines, he investigated the cause of the explosion at the Seaham Colliery in 1881, and its connection with the presence of coal dust in the air.

No account of Abel's career can be complete without some reference to what he regarded as the most important work of his life. From the first he took a leading and responsible part in the movement which led to the foundation of the Imperial Institute. He was the secretary to the first organising committee, and in a lecture delivered at the Royal Institution in 1887 he gave an account of the work which the Institute proposed to accomplish. It is noteworthy that the need for further provision in this country for scientific research in connection with art and manufactures was one of the principal points in this lecture. On the opening of the Imperial Institute in 1893, Abel was appointed its secretary and director, a post which he held, latterly in an honorary capacity, until his death. Although already far advanced in life, Abel threw himself with great courage and determination into the difficult task of organising the operations of the Institute, and continued to do so even in the face of steadily declining health. In relation to the history of the Imperial Institute, it need only be noticed here that in 1894 a laboratory was equipped on a small scale for the chemical examination of Indian and Colonial products. In 1896, a scientific and technical department, including extensive laboratories, was established with Prof. Dunstan as director, but the necessary funds were supplied by the Royal Commissioners of the 1851 exhibition, all the available funds of the Institute having been allocated to other purposes. Although it was Abel's intention to retire from official connection with the Imperial Institute on its transfer to the Board of Trade at the end of the present year, he characteristically expressed his intention of continuing to take an active part in its proceedings as a member of the advisory committee.

Abel was an influential member of many scientific societies. He was elected a Fellow of the Royal Society in 1860, and was awarded a Royal medal in 1887 for his researches on explosives. He became at an early age a Fellow of the Chemical Society, and filled several offices in the Society, in which he was always deeply interested; at the time of his death he was one of the oldest of its past presidents. Abel took a leading part in the foundation of the Institute of Chemistry, of the Society of Chemical Industry and of the Institution of Electrical Engineers, of all of which he became president. He was also president of the British Association in 1890 and of the Iron and Steel Institute in 1891. He had filled the offices of vice-president and chairman of the council of the Society of Arts, which awarded him the Albert medal in 1884. Abel took an important part in the foundation of the City and Guilds of London Institute, and was at the time of his death chairman of its executive committee. He was an influential member of the court of the Goldsmiths' Company, of which he became prime warden in 1895. Abel's distinctions were numerous and varied. He was a D.C.L. of Oxford and a D.Sc. of Cambridge. He was made a C.B. in 1877 and was knighted six years later. The K.C.B. was conferred in 1891, and he was created a baronet on the occasion of the opening of the Imperial Institute in 1893. The last honour, that of the G.C.V.O., was conferred by the King soon after his accession, in recognition of Abel's personal services to the Royal Family.

Highly endowed with a practical mind, great common sense and a prodigious power of work, Abel was invaluable as a member of committees. His large experience in drafting official papers made him an excellent critic, and it may be safely asserted that few of the many documents submitted to him, by the institutions he was connected with, left his hands without substantial improvement. As time went on, routine work became a confirmed habit and the idea of a holiday positively repugnant to him, so much so that he found himself unable at the last to take rest and change, the necessity for which his friends and medical advisers so repeatedly urged on him.

W. R. D.

AN INSTRUMENT FOR AIMING GUNS UNDER COVER.

THE advantage of cover in military operations has been shown over and over again during the recent war in South Africa. But even when cover is available, the head of the soldier is exposed, while in the act of aiming, to the fire of an enemy. By means of the hyposcope the marksman is able to aim with considerable accuracy, while protected by a cover of earthwork or stones. Apparatus for sighting ordnance by means of mirrors has been employed by the war departments of several nations.[1] But the inventor of the hyposcope, Mr. W. Loulten, has dealt with the problem of furnishing any existing rifle with a system of mirrors, whereby the act of aiming may be performed from a point several inches below the trigger-guard. The hyposcope is shown in Fig. 1 attached to the service rifle, which is placed in position over the edge of a rough mass of stones used as cover. The marksman aims the rifle by looking into the mirror at the lower end of the vertical tube, his head being protected by cover. In this form of instrument, four mirrors are employed; on looking into the instrument, the sights of the rifle are

[1] "Treatise on Service Ordnance." (London, 1893).

seen nearly as clearly as under ordinary conditions, the system of mirrors merely translating the line of sight along the rifle, parallel to itself, to the distance of about eight or nine inches below the axis of the barrel of the rifle.

FIG. 1.

In another form of hyposcope, used to sight a Maxim gun, Fig. 2, two mirrors only are employed to translate the line of sight downwards, and but little light is lost. The tube which carries the mirrors is graduated, and the correct elevation is obtained by means of two easily made movements of the apparatus.

The National Rifle Association, recognising the importance of shooting while protected by cover, awarded prizes at the Bisley meeting this year for shooting with the hyposcope sighting. The range was 200 yards, the bullseye seven inches; each man of the thirteen who shot had seven shots. The highest possible score was 35 per man, and the average score per man was 32·15. The apparatus and the method of holding the rifle were new to nearly everyone who shot. In actual warfare, an enemy may approach a trench or cover from any direction, and his approach must be seen, before the rifle is brought to bear on him. Probably the observation of the movements of the enemy might be found approximately by using a separate hyposcope, not attached to a rifle in the usual way, so as to bring into view each portion of the foreground in succession. Such an instrument would only require two mirrors, and would enable an outlook to be kept with a minimum of danger to the observer. The instruments are strongly made, and with reasonable care they should efficiently answer their purpose.

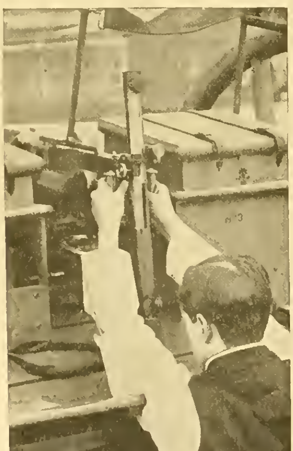

FIG. 2.

THE BRITISH ASSOCIATION AT BELFAST.

IN point of numbers, the meeting of the British Association at Belfast has not been a very large one, but it has certainly been a decided success and has been full of interest. About sixteen hundred members and associates have attended, and in addition many people have been present at the meetings who have not registered their names. The local committee has facilitated the work of the secretaries in every possible way, and the excursions have been a means of pleasure and profit to all who have been able to take advantage of them. No meetings were held on Saturday, so that members should be free to avail themselves of the opportunity of taking part in the interesting excursions arranged for that day.

At the first meeting of the General Committee, the report of the Council was read. Reference to the severe loss the Association has sustained by the death of Mr. Griffith, the late assistant general secretary, was made in the first paragraph of the report, and it was announced that Dr. J. G. Garson had been nominated to succeed him in this important office. Sir William Roberts-Austen, K.C.B., having informed the Council that he did not intend to offer himself for re-election as general secretary, Major P. A. MacMahon, F.R.S., was appointed as his successor, and Prof. D. J. Cunningham, F.R.S., was elected to fill the vacancy thus caused among the members of the Council. In addition to Prof. Cunningham, the following members have been elected on the Council, the new names in the list being in italics:—*Sir W. Abney, K.C.B., F.R.S.*; Prof. H. E. Armstrong, F.R.S.; Dr. J. Bonar; Prof. F. O. Bower, F.R.S.; Prof. H. L. Callendar, F.R.S.; Captain E. W. Creak, R.N., F.R.S.; Major L. Darwin; the Hon. Sir C. W. Fremantle, K.C.B.; Prof. F. Gotch, F.R.S.; *Prof. A. C. Haddon, F.R.S.*; Prof. W. D. Halliburton, F.R.S.; *Mr. C. Hawksley*; *Prof. G. B. Howes, F.R.S.*; Dr. J. Scott Keltie; Sir Oliver Lodge, F.R.S.; Prof. A. Macalister; Prof. W. H. Perkin, F.R.S.; Prof. John Perry, F.R.S.; Mr. L. L. Price; Mr. A. C. Seward, F.R.S.; Prof. W. J. Sollas, F.R.S.; Prof. W. A. Tilden, F.R.S.; *Prof. W. W. Watts*; Sir John Wolfe-Barry, K.C.B., F.R.S. Profs. H. Elster and J. Geitel have been elected corresponding members of the Association.

At the second meeting of the General Committee, Sir Norman Lockyer, K.C.B., F.R.S., was elected president of the Association next year. The meeting will be held at Southport, and will commence on September 9, 1903. It was resolved to hold the meeting of 1904 at Cambridge, and in all probability the meeting of the following year will be held at Cape Town. The invitation to visit South Africa has been backed up by the promise of substantial pecuniary support, so that a large and representative number of members of the Association may be enabled to accept it.

The following grants of money for scientific purposes were recommended by the General Committee at the meeting on Monday:—

Mathematics and Physics.

Rayleigh, Lord—Electrical Standards	£35
Judd, Prof. J. W.—Seismological Observations	40
Shaw, Dr. W. N.—Investigation of the Upper Atmosphere	75
Preece, Sir W. H.—Magnetic Observations	40
Chemistry.	
Divers, Prof. E.—Study of Hydroaromatic Substances.	20
Roscoe, Sir H. E.—Wave-length Tables of Spectra ...	5
Geology.	
Herdman, Prof.—Fauna and Flora of British Trias ...	5
Marr, Mr. J. E.—Erratic Blocks	10
Scharff, Dr. R. E.—To Explore Irish Caves	40
Watts, Prof. W. W.—Underground Waters of North-West Yorkshire	40
Marr, Mr. J. E.—Life-zones in British Carboniferous Rocks	5
Geikie, Prof. J.—Geological Photographs	10
Zoology.	
Herdman, Prof. W. A.—Table at the Zoological Station at Naples	100
Woodward, Dr. H.—Index Animalium	100
Geography.	
Keltie, Dr. J. S.—Tidal Bore, Sea Waves and Beaches	15
Holdich, Sir T.—Scottish National Antarctic Expedition	50
Economic Science and Statistics.	
Brabrook, Mr. E. W.—Economic Effect of Woman's Labour	25
Mechanical Science.	
Preece, Sir W. H.—Screw Gauges	5
Binnie, Sir A.—Resistance of Road Vehicles to Traction	90
Anthropology.	
Evans, Sir J.—Researches in Crete	100
Read, Mr. C. H.—Exploration of Stone Circles ...	5
Cleland, Prof. J.—Anthropometric Investigation ..	5
Ridgeway, Prof.—Anthropology of the Todas and Tribes of Southern India	50
Read, Mr. C. H. — Anthropological Photographs (balance in hand)	—
Physiology.	
Halliburton, Prof. W. D.—The State of Solution of Proteids	20
Botany.	
Miall, Prof. L. C.—Registration of Botanical Photographs	3
Farmer, Prof. J. B.—Investigation of the Cyanophyceæ	25
Ward, Prof. Marshall.—Respiration of Plants	12
Educational Science.	
Sherrington, Prof.—Conditions of Health essential for School Instruction	10
Corresponding Societies.	
Whitaker, Mr. W.—Preparing Report, &c.	20
	£960

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY EDWARD DIVERS, M.D., D.SC., F.R.S., V.P.C.S., EMERITUS PROFESSOR OF CHEMISTRY IN THE IMPERIAL UNIVERSITY OF TOKYO, JAPAN, PRESIDENT OF THE SECTION.

The Atomic Theory without Hypothesis.

IN opening the Chemical Section of the British Association in this city and in the halls of the Queen's College, my first words must be those of reverence for the memory of Thomas Andrews, for so many years the Professor of Chemistry in this College, whose investigations into the properties of gases—above all, those which resulted in the recognition and determination of the critical pressure and temperature of carbonic anhydride—have become a part of the foundation of the Kinetic Theory of Gases. At the Meeting of the British Association here in 1852, Andrews was President of this Section, and again at the Meeting in Edinburgh in 1871.

Since the Meeting last year another distinguished chemist, formerly professor in one of the Queen's Colleges, Maxwell Simpson, has also passed away. He, too, acted as President of this Section, namely, at the Meeting in Dublin in 1878. The work by which Simpson's name will ever be recalled is more especially that upon the synthesis of polybasic organic acids.

One other name must not be left unmentioned in this Address: it is that of a long-time Fellow of the Chemical Society who has been intimately connected with the British Association—I mean that of George Griffith, the genial and most effective Assistant General Secretary of the Association for so many years, who died four months ago. He had visited Belfast in the spring and made the preliminary arrangements with the Local Committee for this Meeting. He joined the Chemical Society in 1859—just one year before I did—and remained a Fellow until his death.

It is now almost a century ago since John Dalton made known to the world his theory of the nature of chemical combination by the publication of a table of atomic weights. He had been occupying himself for some years with the study of the physical properties and atomic constitution of gases before he was led to extend the notion of the atom to chemical phenomena, and thus to form that conception which was to become celebrated as the atomic theory. In his laboratory note-books, preserved from 1802 onwards, the publication and analysis of which we owe to Sir Henry Roscoe and Dr. Harden, no reference is made to the theory till 1803, but we may well believe with Henry that it was already in Dalton's mind just a hundred years ago. But however that may have been, it seems fitting in a year so closely approaching the centennial of its publication as the present that the occupier of this Chair should address his audience on a subject of such general interest and importance as the atomic theory, if indeed there remains anything to be said on a subject which has so long and so fully engaged attention.

I dare not assert that I have found anything actually novel to bring before you with regard to the atomic theory, but I may say that there has certainly long seemed to me to exist the need to treat it as being a true theory instead of as an hypothesis, and to teach it and discuss it accordingly.

In thus setting forth what appears to me to be the proper form of the atomic theory, I shall have, at the risk of overtaxing your patience, to restate and examine most of the fundamental and familiar principles of our science in order to illustrate and justify the view I take. Not only this, but in order as directly and briefly as possible to meet the objection that whatever the atomic theory may be it cannot be introduced to the student of chemical philosophy in another form than that now in use, I shall sometimes have to adopt, in order to show what can be done, a didactic method which, in most other circumstances, would be quite inexcusable before so distinguished an assembly.

The atomic theory of chemistry stands unsurpassed for the way in which it has fulfilled the purpose of every great theory, that of giving intellectual mastery of the phenomena of which it treats. But in the form in which it was enunciated, and still is universally expressed and accepted, it has the defect of resting upon a metaphysical basis, namely, upon the ancient hypothesis that bodies are not continuous in texture, but consist of discrete, ultra-minute particles whose properties, if known, would account for those of the bodies themselves. Hence it has happened that, despite the light it throws upon the relations of chemical phenomena and the simple means it affords of expressing these relations, this theory has always been regarded with misgiving, and failed to achieve that explicit recognition which its abounding merit calls for. Indeed, the desire has been expressed to see the time when something on a more solid foundation shall have taken its place.

Now, it is not my intention to discuss the merits or demerits of the atomic hypothesis, which can indeed no longer be treated as a merely metaphysical speculation. What I would do to-day is to impress upon you that, in spite of all that has been said and written about the atomic hypothesis in connection with chemistry, the atomic theory propounded by Dalton and adopted, implicitly at least, by all chemists, is not founded upon the metaphysical conception of material discontinuity, and is not explained or illuminated by it. For if that should be the case there will no longer exist any grounds for hesitation in accepting

the theory quite explicitly, and then the anomalous condition of things will be removed of a theory being in universal use without its truth being freely and openly admitted. For the sake of clearness, it is convenient to restrict the term "atomic hypothesis" to the old metaphysical view of the discontinuity of matter whilst applying the term "atomic theory" to the current elaborated form of the Daltonian theory; this distinction is adhered to in the present Address.

In the peroration to his admirable discourse upon atomic weights or masses delivered before the Chemical Society in 1892 as the Stas Memorial Lecture, Prof. Mallet, F.R.S., said: "By the chemist at his balance the arm of reason is directed into those regions of almost inconceivable minuteness, which lie as far beyond the reach of the most powerful microscope as that carries us beyond the reach of the naked eye, quite as impressively as that same arm is stretched forth by the astronomer at his divided circle to reach and to weigh the mighty planets that shine in the remotest regions of our solar system." On two occasions I have heard the same comparison between the chemist and the astronomer made by Lord Kelvin when he was in the company of chemists; and undoubtedly both these high authorities have only then expressed the general view as to the nature of the domain of the chemist. Yet I venture to question whether there is anything in the ways and work of the chemist to support such a view and give point to Mallet and Kelvin's comparison. If, indeed, chemistry is a science which rests upon the atomic hypothesis and, therefore, would cease to exist in the form into which it has developed should matter prove to be continuous and not discrete, nothing can be said against the view that it is a science of the minute. But I am sure there can be no one ready to maintain that, if the hypothesis of the atomic constitution of substances were an unfounded one, the atomic theory would have been a discovery of no great importance; and Dalton himself, instead of being the founder of the chemistry of to-day, have been little more than the discoverer of the law of multiple proportions. If that cannot be maintained, what, then, becomes of this conception of chemistry as dealing with the minute? So far as comparison can be made between the operations of the astronomer and the chemist, it is the former and not the latter who, as a matter of fact, deals with the almost infinitely minute. For if, indeed, the chemist often works upon comparatively small amounts of substances, and, consequently, with very sensitive balances, that is, as we all know, only for reasons of economy of time, materials and apparatus; otherwise he works on the largest possible scale, with the object of attaining to the highest degree of accuracy and perfection. The astronomer, on the other hand, has, perforce, to deal with the smallest visible things in nature, the nearest approach there is to geometrical points, those fixed points of light in the heavens which are only known through scientific investigation to be other than what they seem to be. It is, therefore, only as interpreted by the atomic hypothesis that chemistry can be said to deal with the minute.

When the atomic theory is expounded in the usual way it is commonly and correctly stated that, on the assumption that substances consist of minute indivisible particles having weights or masses bearing the ratios of the combining numbers assigned to them, the laws of chemical combination by weight necessarily follow, and are thereby explained. But then the converse is not true—that because chemical combination obeys the well-known laws, substances consist of discrete particles. Nor does the assumption of the truth of the atomic hypothesis afford any real explanation of the facts expressed by the laws of chemical combination, or more comprehensively by the atomic theory, when that theory is given in non-hypothetical terms. It is just as difficult to see why the atoms should possess the weights on chemical grounds assigned to them as to see why substances interact in the proportions that they do; that they do do so is, in either case, an ultimate fact, for which no explanation has presented itself. The atomic hypothesis masks this ignorance and deadens inquisitiveness. Notwithstanding all this, which is incontrovertible, it is certainly a common opinion that in chemistry we investigate the minute and intimate constitution of things.

But if, after all, chemistry does not deal with the minute, or, rather, if it has no concern with the magnitude of single bodies or their molecules; if the atomic hypothesis is not the foundation of, or necessary to, the atomic theory, then it is certainly most desirable and important that the theory of chemistry, which, with all its modern developments, I take to be indisputably the atomic theory of Dalton, should be held and expounded without any reference to the physical constitution of matter, in so far as that remains unknown. The opinion that chemical theory should be developed without reference to the atomic hypothesis has indeed all along been held by many eminent chemists; but then the dilemma appears to have presented itself to them, that either the atomic hypothesis must be granted or the atomic theory must be dispensed with, since it falls with the hypothesis. That dilemma I do not recognise, and the practice of chemists shows beyond doubt that it is always ignored. Investigators use the theory whether they admit it or not; teachers of the science find it indispensable to their task, however much they may deprecate, and rightly so, unreserved acceptance of the atomic hypothesis as true.

Refusing to commit themselves to belief in the hypothesis, chemists have thought from the first to escape the adoption of the atomic theory by putting Dalton's discovery into something like these words: Numbers, called proportional or combining numbers, can be assigned to the chemical elements—one to each—which will express all the ratios of the weights or masses in which substances interact and combine together. Perhaps the atomic theory is here successfully set aside by expressing what is an actuality as an unaccounted-for possibility. But then those who use any such mode of expressing the facts, without reference to the theory, never fail also to adopt the doctrine of equivalents, and thus, by this double act, implicitly give in their adherence to the theory.

Divested of all reference to the physical constitution of matter, the atomic theory is that the quantities of substances which interact in single chemical changes are equal to one another—as truly equal in one way as equal masses are in another—and, therefore, that chemical interaction is a measure of quantity of unlike substances, distinct from and independent of dynamical or mass measurement.

Dalton, indeed, did not express himself in any such terms, his mind being fully possessed with the ancient and current belief upon which he framed his theory that substances are made up of minute, discrete particles. But it is clear enough that his theory was that of the existence of another order of equality between substances than that of weight. Up to his time, the weight or mass of every ultimate particle of any substance whatever appears to have been assumed to be the same, the atoms being alike in every way. That assumption is still made by many thinkers, chemists among them; we meet it, for example, in the different forms of the hypothesis that the elements are all, in some way, physically compounded of a universal and only true element, as in Prout's hypothesis. Dalton saw things differently, and recognised that, on the assumption of substances being constituted of particles which never subdivide, weight or mass cannot be the same for every such particle, except in the case of those of any one simple substance. Therefore, having given some numbers showing what he believed to be the respective weights of the atoms of several simple substances, taking that of hydrogen as of unit-weight, he proceeded at once to invent symbols for these atoms to indicate, not only their distinctness in kind, but above all things their indivisibility and their equality, properties which the use of their atomic numbers would have inadvertently concealed or even apparently denied, and could never have expressed or connoted.

It was only in this immediate invention and use of chemical symbols that Dalton's conception found clear expression; and again it is by the universal adoption of such symbols that chemists have shown their real acceptance of the atomic theory, even while displaying, not infrequently, their scepticism as to its truth. The replacement by Berzelius of Dalton's marked circles for atomic symbols by letters which should recall the names of the substances was in a way a great improvement, but it has had the serious consequence of causing chemical symbols to be usually first brought under notice merely as serviceable abbreviations for the names of the elements, and only then described as representing their atomic quantities. Now, evidently, what the character used as symbol shall be is, theoretically considered, but a petty detail; the vital point is what the character symbolises, and that is the atom. It does not symbolise the name; it only indicates that and recalls it. It may be said, indeed, to represent the atomic number, since it stands in place of it; but it is made to do so only in order that we may for the time forget this number and have in mind the integral character of the atom. It is not the 4006 parts of sodium hydroxide and 8097 parts of hydrobromic acid, or approximately twice as much of the latter

as of the former; it is not these gravimetrically expressed interacting quantities that we are to think of when the formulæ NaOH and HBr are before us, as we too often strive to do; it is not these, from a chemical point of view, meaningless numbers of parts, but quantities which are equal in the sense of chemistry, that are expressed as such by these symbolic formulæ. The real purpose of chemical formulation is not to abbreviate or replace language, but to facilitate, if not ensure, abstraction from and non-contemplation of gravimetric numbers.

I have just passed from atomic symbols to the formulæ of molecules; but this was not without warrant. In the form in which I have enunciated the atomic theory, it relates to the chemical interaction of substances, whether compound or simple, and the equality of the quantities concerned is the equality of molecules, since these are the quantities of substances entering into or coming out from single chemical interactions. Were it not, therefore, for fear of confounding it with the mechanical theory of that name, the atomic theory should be called the molecular theory of chemistry. It might, indeed, have happened to be so called by its author, for Dalton has told us that he had in mind both atom and molecule as names for his chemically ultimate particles, and chose the former because it carried with it the notion of indivisibility. He extended, also, as we do, the use of the term "atom" to chemically compound substances, since their combining quantities are chemically indivisible.

Next, I would point out that in the atomic theory the notions of indivisibility and equality are inseparably involved. The indivisibility of atom and molecule is not absolute or ultimate, and Dalton distinctly guarded himself against being understood to claim for the atom more than chemical indivisibility, and chemists of to-day assert no more than this. This indivisibility being conditioned by the equality of molecules, the importance of emphasising it rests only upon the danger, when it is overlooked, of losing sight also of the chemical equality through the gravimetric inequality receiving numerical expression, and thereby conveying the notion of divisibility, though only gravimetrically. The idea of indivisibility in connection with the atom or molecule is intrinsically quite subordinate to that of equality; for equality, being unity or oneness brought into relation with itself, the conception of it carries with it and includes that of indivisibility. Any rational hypothesis as to substances consisting of ultimate particles will include the notion of their being indivisible particles; and the import of the hypothesis in chemical theory must lie, therefore, not in this indivisibility, but in the nature of the equality of the particles. By his atomic theory Dalton asserted that where the substances are different this equality is chemical instead of gravimetric.

Molecules are equal in the sense that they are quantities of their substances which are interdependent and coordinate in any and every single chemical change in which they take part together. It is a form of equality for which no close parallel can be found; but as to that it should be remembered that this equality relates to the phenomena of the transformations of substances into each other, which, though they form so large a part of the phenomena of the universe, are fundamentally distinct in nature from the rest of the behaviour of bodies throughout which the substance remains what it was. In some agreement with it there is that of mechanical pressures when these balance or neutralise each other, and therefore are opposite and mutually destructive though equal. But such pressures when exerted in the same direction are also equal in their effect on any body in their path, whereas in chemical interactions the effects of molecules or equal quantities of two unlike substances are only equal in the sense that each is that quantity which interacts with the same quantity of some third substance, which itself proves to be also a chemically equal quantity to them. For the products of the interaction in the one case are in part at least not the same as those in the other, though all prove chemically equal in further interactions.

To give an example: the molecule of ammonia is equal to that of aldehyde in that it combines with it and with it disappears, or ceases to exist as such. For the same reason it is equal to the molecule of hydrocyanic acid, and molecules of aldehyde and hydrocyanic acid equal to each other, because they, too, combine and disappear as such in doing so. But the molecule of ammonia again equals that of aldehyde in effecting transformation of hydrocyanic acid and its own self into something else. And lastly, chemically equal or molecular are the products of these combinations; aldehyde ammonia, ammonium cyanide and aldehyde-cyanhydrine, not only among themselves, but also with the quantities of ammonia, aldehyde and hydrocyanic acid from which they come and into which they return in other chemical changes. But with all this quantitative equality in transforming power, the substances produced are unlike and, each to each, peculiar to one of the three acts of chemical combination; and on this account exception may be taken to the treatment of molecules as equal chemical quantities. Yet the equality of molecules here asserted is but an extension of what is meant by the equivalence of certain atoms and radicals, since the atom and the radical are, nowadays, conceptions entirely dependent upon and derived from that of the molecule (apart, of course, from the atomic hypothesis); and this universally allowed equivalence admittedly does not extend to the identity of the products of the replacing activity of the atoms and radicals.

Quantitative equality and equivalency, it is true, have not the same meaning, equivalence being used to denote qualified equality, equality in certain specified ways, of quantities not equal in all other ways and possibly in no other. Quantities of different substances cannot, strictly speaking, ever be equal, and can only be styled so in the sense of being equivalent; for were they equal in every way the substances would obviously be the same. But this fact, if it ever strikes one, is ignored by universal custom, and quantities of substances, however unlike—feathers, air, water, salt, and what not—are taken to be all equal, even by chemists as by the world at large, if only they have the same weight, notwithstanding the incongruities of the substances. I proceed now to show the baselessness of this conviction, but only to bring out more strongly the claim of chemical activity to equal rights with weight or mass in determining what are equal quantities of substances, for I am aware that here I have nothing to tell you that you do not already know. Weight being only the gravitational measure of mass, which itself is independent of it, quantities of substances are held to be equal when their masses are equal. Now, mass is quantity of matter. But what then is meant by matter? The answer must be either that it is a general term for any and all substances, or else that it is the common basis of all substances, which presents itself in all the different forms which are known to us as such, by virtue of a corresponding variety in its intestinal motions. I gladly pass over the latter answer without discussing it, on the ground that it introduces the subject of the intimate constitution of substances, which it is my set purpose to keep independent of in this discourse. I will only say of it that it would probably be the answer of many physicists and chemists, and yet that it gives such a limitation to the nature of matter as makes the common expression "constitution of matter" devoid of all meaning. That expression means, and can only mean, the constitution of substances in common; and this brings me to the first answer, that matter is the term standing for all substances in common. Now, one thing which all substances possess in common is the property of resisting pressures; pressures not only of moving bodies, but of the motions of the ether and electrons. Measured or quantified, resistance becomes mass, all that can be signified by this term being the quantity of the resistance or inertia a substance exhibits when tested. It is the measure of a property of the substance, that is all; and there is no other way of quantifying a substance than through some one of its properties. No quantities of different substances can, as such, be commensurable throughout; and when compared and measured through some common property, such as the possession of mass, the equivalence or pseudo-equality found by this means is not the same as that found when some other common property is taken as the means of measurement. But experience has shown that though there are several rational and comprehensive ways of instituting, through some common property, comparisons between quantities of different substances, they all, with the exception of that of weighing, agree more or less exactly in pointing to the same order of equivalence, that of chemical activity; for with this are colligated those of gaseous volume and the other well-known physical activities, which give nearly the same quantities as it gives of different substances as being molecularly equivalent. There are, therefore, essentially only two measures of quantitative equivalency or pseudo-equality between substances, the dynamical and the chemical or molecular, the one wholly independent of and the other wholly dependent upon the particular nature of the substances compared. The former is the measure of dynamical phenomena, those of changes of bodies, due to their impacts and pressures, which may lead to their deformation and disruption, but do not involve transformations of the

substances of the bodies into others; the latter is the measure of chemical phenomena, those of changes of bodies induced by such of their interactions as do involve transformations of the substances of the interacting bodies into other substances. Since it is already settled for us by custom that quantities of different substances are to be called equal when or because they are equivalent gravimetrically, and as it is not to be supposed that we shall ever give up calling 16 kilos. of oxygen, of salt, of chalk, and of every other substance, however unlike, equal quantities of them from the gravimetric point of view, we have no choice but also to call molecular quantities of these substances equal from the chemical point of view, if the claim to coordination in equality of chemical with gravimetric equivalency is to be asserted and maintained.

The contention that chemical equality must be regarded as of as clearly defined a nature as gravimetric equality becomes the more weighty when it is reflected that our very definite views concerning gravimetric equality are due solely to the law of conservation of mass, the evidence for and against which, I may remind you, is just now to be discussed by Lord Rayleigh before the Physical Section. The mass of one pound of sodium remains unchanged when the metal is converted into salt, washing soda, or borax; if this were not the case, gravimetric equality would be just as definite as it is now, but physicists would have to argue for its general recognition in much the same way as I am doing now for the recognition of chemical equality.

In further justification of this claim of chemical equality to coordinate rank with dynamical equality in the quantification of substances, it may be well to take the fact into consideration that the determination of the former is independent of that of the latter. Overlooking the difficulties of the task, let there be at hand or always procurable unlimited numbers of parcels of the different substances to be experimented upon, each of which, by other means than weighing, such as spatial measurement, can be known to be equal to, or greater or less than, other parcels of the same substances. Suppose, now, that after many trials, one of a number of equal portions of sodium hydroxide has been found to be the quantity just necessary to interact with one of a number of portions of hydrochloric acid also equal among themselves. The products of the interaction will be some water and some salt. We can now have placed before us a parcel of sodium hydroxide equal to that previously used, another of hydrochloric acid also equal to that used, and the water and the salt obtained, and then have before us chemically equal quantities of four substances. Let now, by spatial measurement, a number of parcels of water be portioned out, all equal to that of the water obtained, and a number of parcels of salt equal to that of the salt obtained. By a series of trials we find a quantity of silver nitrate just sufficient to interact with the sodium chloride, and having, by supposition, taken this quantity of silver nitrate from a lot of other parcels equal to it, we find that one of these is just sufficient to interact with one of the portions of hydrochloric acid equal to that used in producing one of the portions of salt. Further, we find that the salt and the hydrochloric acid each produce a substance which is the same, namely, silver chloride, and in the same quantity as the other. Along with it in the case of the salt is sodium nitrate, and in the case of the hydrochloric acid, nitric acid. We can then find that this quantity of nitric acid is just enough to interact with one of those of sodium hydroxide, and thereby produce quantities of sodium nitrate and water, respectively equal to those obtained in the other interactions. If now we conjoin with these experiments others in which hydrogen, sodium and silver are each caused to combine with chlorine, and others in which hydrochloric acid, silver chloride and sodium chloride are electrolysed into these elementary substances, evidence is obtained of such facts of chemical composition and decomposition and of double decomposition (or what happens when compounds interact) as those upon which the science of chemistry is framed.

In teaching chemistry the point is kept too much in the background, if not altogether out of sight, that the chemical equality of quantities of different substances is independent of all other relations of equality between them, and that, therefore, its validity is not affected by the fact of its terms agreeing with some and not with other terms of equalities determined in other ways. Instead of bringing out this point the molecule of water is given out as being, primarily and prominently, that quantity which has eighteen units of mass and which measures two unit volumes. Both statements happen in the nature of things to be true, but neither of them describes the molecule. Let it be clearly understood from illustrative examples what is meant by "chemically equal," and there is hardly more to be said as to what constitutes a molecule of water than that it is the quantity of it chemically equal to that of some other substance presenting itself for comparison. "Molecule" is a term of relation: it stands for an equal quantity, not for any particular quantity; but as such it is as easy to understand and as indefinable as an equal volume or an equal weight of a substance.

It is then only as colligated equalities, established by experiment, that gaseous volumes, osmotic pressures and other properties of substances come into consideration, first as enforcing the truth of the conception of the indicated quantities as equal, and then as the means of molecular measurement without resort to chemical change. But of the purposes served by the colligative properties, that of giving molecular measurements without recourse to the evidence afforded by chemical change is well known to be of the very widest application. To determine chemically the molecular equalities of substances, single chemical changes of suitable character, changes which are cases of double decomposition, have to be looked for; and to know these with the desirable degree of certainty calls for a much larger acquaintance with the chemical behaviour of the substances than can usually be gained at the early stage of work when the knowledge of the molecule is of the utmost assistance in the further investigation of the nature of the substances. Consequently, it is nearly always through recourse to physical methods that the molecule is first ascertained, and then through the molecule the certainty acquired that some particular interaction is a single one, thus reversing the normal order of things, which undoubtedly is that the molecule in chemistry, however it may have been first determined, is recognised as such by being what it is in chemical change.

I shall have been wholly misunderstood by you if you suppose that I would make light of the importance of the balance in chemical operations, or of the value of its indications in chemical investigations. Once the weights of molecular or atomic quantities have been ascertained the balance becomes the most accurate and generally the most easily applied instrument for apportioning substances in these quantities. Chemical interaction, to be employed in this way and without the aid of the balance, is practically useless, for the reason that it involves the destruction of the quantities it measures. Out of this dependence on the balance arises the exceeding importance of accurate tables of atomic weights, from which molecular weights are derived by addition; but the place for these tables is not on the walls of the lecture-theatre, but in the laboratory pocket-book, and, perhaps, in the balance-room. Besides the use of the balance and of atomic weight tables for getting and calculating out molecules of different substances at pleasure, there is the indispensable service they perform in enabling chemical analysis to be carried out and applied to the solution of the problems offered by chemical change. The primary problem of every science is to find some element of sameness in the diversity of its phenomena, in order that they may be compared, a problem which was solved for chemistry to a large extent by Dalton, and ceased to exist when the distinction had been made between molecule and atom. But this having been solved, there comes the other problem, namely, to find definite, that is, quantitative differences in the midst of the uniformities, and these for the chemist are differences of mass or weight. Through that redistribution of mass which attends chemical interactions, it has been possible to trace out to some extent the nature of the transformation of substances and develop the science on the lines of chemical composition and chemical constitution. Thus, then, the balance has become and will continue to be the necessary instrument of chemical research; but again I would remind you that it records its facts in units which are not ours, and of which we avail ourselves only as the means to an end. Sodium chloride is chemically composed, not of 3545 equal parts of chlorine with 2305 of the same equal parts of sodium, but of equal quantities of these simple substances.

The theory of chemical molecules or equalities and their relations to the equalities between the weights and gaseous volumes of different substances were brought to light, not by Richter's law of chemical combining proportions, and not by Avogadro's hypothesis as to there being equal numbers of particles in the same volume of different gases, but in the first place by Dalton's atomic theory and Gay-Lussac's law of simply related gaseous volumes in chemical change; and then, much

more fully in the middle of the last century, through the brilliant work of Gerhardt, Williamson, Laurent, Odling, Wurtz, and others, in the purely chemical field. Dalton gave us the conception of the molecule, though confused with that of the atom, as the unit of measure of chemical activity in place of the gravimetric unit; the work of the chemists of the last mid-century gave us a fuller conception of the molecule, along with the notion of chemical change as being substitution in the molecule effected by what became known as double decomposition. Up to that time chemistry had been treated only as the science of compounding and decompounding or reducing. Sodium added to oxygen gives soda, sulphur added to oxygen gives sulphuric anhydride, soda added to the anhydride gives sodium sulphate, ethylene added to chlorine gives dichlorethane, water subtracted from alcohol leaves ether, and so forth. All this is strictly true in a limited way, but then it is not chemistry: and the addition precedes and does not constitute the chemical union. In the sodium sulphate we perceive no soda, no anhydride, no sodium, sulphur or oxygen. That is to say, there is evidence of the addition and subtraction of mass and some other such evidence; but, for the rest, evidence of addition there is none. Were it otherwise there could be no chemistry. It is true that one of the great things accomplished by chemistry has been that of establishing the law of the conservation of mass, without which to rely upon the chemist would be unable to carry on his experimental investigations. But that is only because, like the steady point to the seismologist, it is there unchangeable when all else is changing. Since it is the law of no change, it cannot serve to explain what is change. Far from being the science of the composition of substances, chemistry might be defined as being the science of the non-composition of substances where that composition might have been looked for from the antecedents. If salt is verily a compound of sodium and chlorine, and can be broken up into these, why have the fragments not the marks on them of that whole of which they formed a part? It is true that 5850 parts of salt become 3545 parts of chlorine and 2305 parts of sodium, nothing being gained or lost in weight; but to account for that there is no need of chemistry, a science which takes cognisance of the phenomena of change, and not of those of unchanged properties. The use of the word "composition" in chemistry cannot be discarded now, and all that is necessary to make it unobjectionable is to see that the term is always qualified by the prefix "chemical" when there is a possibility of mistake about its significance, and that that significance is carefully explained, if not defined and fully illustrated, before it is given over to the beginner.

The facts of a chemical nature about common salt which cause the statement to be made that it is a chemical compound of chloride and sodium are such as these. Salt can be wholly changed into sodium and chlorine; these substances brought together change into salt and nothing else; salt and sodium, each under conditions appropriate to it, change into the same substance, called also a sodium compound, such as sodium hydroxide; salt and chlorine, each in its own way, change into the same chlorine compound, such as hydrochloric acid; neither sodium nor chlorine, one apart from the other or the other's chemical compounds, ever changes into salt; salt is, directly or indirectly, producible in the chemical interaction of a sodium compound with a chlorine compound; the properties of salt are much less like those of either sodium or chlorine than like those of some other substances; in sensible and other physical properties the chemically compound substance, salt, is as simple as or simpler than either of the chemically simple substances, sodium and chlorine; lastly, the laws of combining proportion by weight are obeyed in all the chemical changes in which salt takes part.

With exclusive reference to such facts as these, the chemical composition of a substance will, I think, be found to be satisfactorily defined, as its having the power, capacity or property of being wholly producible from and wholly convertible into, directly or indirectly, those substances of which it is said to be composed. A simple substance differs from one that is compound only in not possessing the power of being by itself convertible into two others, or of being produced alone from any two others. Simple substances are not less varied or less complex in their physical properties than compound substances, while their chemical constitution is often more problematic than that of many which are compound. The term "simple," therefore, is as misleading in the language of chemistry as "compound," unless defined and qualified in use by the word "chemically."

The ground really occupied by chemical composition in theoretical chemistry is now greatly limited; for with the full acceptance of the idea of the molecule and of the atom as a derivative of it, its place has been taken by chemical constitution to an extent hardly realised. The useful and practically necessary expression of the results of the quantitative analysis of a new substance gravimetrically is all that can strictly receive the name of its chemical composition. When the term is applied more widely it is used for what are really the simpler forms of chemical constitution. It was otherwise before the conception of the molecule had become current and the atom had become a derived function of the molecule. Chemical composition as expressed by Dalton in atoms is indeed that and nothing else. Carbonic anhydride is composed, according to him, of two atoms of oxygen to one of carbon, as against carbonic oxide, which is composed of one; marsh gas of two atoms of hydrogen to one of carbon, as against olefiant gas composed of one. But then it was only numerical necessity which led him to adopt such a mode of expressing the facts. The same necessity, it is true, affects us also in the matter of carbon dioxide, of water and of ammonia, but how little it does so is shown by the many cases in which the empirical or simple composition is expressed in multiples. The atomic chemical composition of ethylene is two of hydrogen to one of carbon, and that of benzene one of hydrogen to one of carbon. When we say, as we always do, that the one substance is "composed" of four atoms of hydrogen to two of carbon, and the other of six of hydrogen to six of carbon, we give what is information concerning the constitution of these substances. Call it the composition of the molecule as we may, it is evident that by composition we can here mean only constitution. As with polymerism, so with isomerism, and in a more marked way. Mercurous sulphate and mercuric oxysulphite, quite distinct salts, have yet the same composition.

In the great reformation wrought by the chemists to whom I have referred, but by Gerhardt in particular, the new light set up in chemistry was the notion of what came to be called "double decomposition" in chemical change. The phrase is not, perhaps, happily constructed, but it has the merit of needing some explanation of its meaning before it can be understood, and troubles, therefore, through a too simple apprehension of the sense of the word "composition" are hardly to be feared. Its introduction into chemistry marked the ascendency of the idea of the molecule as the factor in chemical change whose interactions with other molecules were to be considered, instead of those additions which, as chemical phenomena, never take place. It led also to new conceptions of the nature of the atom and the compound radical as being the quantitative and qualitative expressions of the powers possessed by substances to change into others, and to the conception of the valency of atoms and radicals as expressing the nature of the connection of successive chemical changes. The zeal with which it was attempted to force all chemical changes into the form of double decomposition interfered, perhaps, with the full recognition of its importance; but the fact remains that, with hardly an exception, all that is stated concerning the nature of those chemical changes in which two or three substances become one, or one becomes two or more, is based upon notions derived from the study of double decomposition.

The fundamental value of double decomposition consists in its displaying threads running through chemical transformations which can be followed up. When two substances change into two others, and only then, there can be found, in most cases, relations of resemblance, both physical and chemical, between the before and after of a chemical change. Instead of the striking unlikenesses shown by the substances formed by quasi-addition to those from which they are formed, there are here met with the similarities of the outcoming to the interacting substances, and the similarities between the products of different interactions in which the acting substances are similar. Chemists had been for very long familiar with acids, bases, salts, without becoming deeply impressed with the significance of the resemblances which these class-names imply, and also with the facts that acids beget acids, bases bases, and salts salts, or in more general terms, that substances in interaction produce others like them, and that differences between the products and the agents in one change are distinctly repeated in a similar change in which other substances are concerned, points now given expression to by such terms as "chemical constitution," "homologous" and "analogous series," "Kopp's law," &c.

What is so important to consider in the study of double decomposition is that the fact, that the sum of the masses of the two products of the change is the sum of the masses of the two interacting substances, presents itself no longer as being merely the evidence of the massing together of substances into a compound; for there is in double decomposition to be considered that redistribution of mass which, on the one hand, is found to correspond to and be part of a general though not sharply defined redistribution of physical and chemical properties; and, on the other hand, to be obviously irreducible to that interchange of those simpler substances which in many cases are produced in the simple decomposition of the acting substances.

The physical properties of substances, or rather their sensible qualities, are of too uncertain a character for their redistribution to be safely traced. But it generally does result, amongst inorganic substances, at least, that colour is transmitted, the saline, acid, bitter, or other taste of one of the active substances will appear, with more or less distinctness, in one of the products, a relatively volatile and a relatively fixed substance together will yield a similar pair of products, a dense and a light substance will yield a dense and a light substance, and so on. The chemical properties, however, are quite definitely redistributed to a large extent, a fact sufficiently illustrated by saying that an iron salt yields an iron salt, and a sulphate yields a sulphate.

But this is not a redistribution in which simpler substances, or indeed any other substances than those interacting, play a part; as soon becomes evident on attempting to establish the contrary by an appeal to the facts. While silver acetate and silver sulphate resemble each other and also silver nitrate as silver salts, they do not resemble silver itself; and though silver nitrate resembles sodium nitrate as nitrate, there is not even a substance known which is related to these salts as silver is related to silver salts. It might be objected to this that there may yet become known such a substance, which in its ultimate decomposition would give one molecule of nitrogen to three molecules of oxygen. If instead of nitrate were given acetate or cyanide, there would be found in the substances acetic peroxide and cyanogen, it might be said, the analogues of the as yet unknown substance of the nitrate. But the point I would make is that nitrate, sulphate, &c., are names with well-defined meanings independent of the fact that the corresponding substances are not known; for it follows without argument that also the terms silver, iron, chloride, &c., should be equally independent in meaning of the existence of the substances silver, sodium, chlorine, &c. It is a familiar historical fact that cæsium, helium and fluorine were chemical names long before the substances cæsium, helium and fluorine became known. We might well be convinced, therefore, without going further, that constitutional names, names which convey the facts of likenesses preserved in chemical change, cannot be indicators of the presence of the substances for which they may be also used. For, that being the case, we have no grounds for assuming that silver nitrate in interaction with sodium sulphate decomposes into the substance silver, which then combines to form silver sulphate. But fuller proof than any appearance of likeness or unlikeness can give is afforded by facts which became known and appreciated in connection with the chemical molecule. Typical of them all is the fact that in none of its interactions does chlormethane yield a hydrocarbon simpler than methane or than itself. Under those conditions in which it might have been expected to give a substance which would be methyl, it produces ethane, a substance which chlorine converts into another substance, having instead of one-third only one-sixth less hydrogen in its composition. Similar results have been obtained in all cases where the point can be determined—that is, where the simpler substance looked for would still be a compound substance, and such simpler derivatives are looked for no longer. The monohydride of oxygen or sulphur, the dihydride of nitrogen or phosphorus or arsenic, the mononitride of carbon, the organic compounds, methyl, phenyl, acetyl, are not only unknown, but are held to be non-existent substances, though their chemical compounds, the hydroxides, amides, cyanides and the rest are both numerous and well defined. Whatever other view we shall have to take of the constitution of Gomberg's remarkable "triphenylmethyl," it will certainly not be that it is identical with the radical of the triphenylchlormethane from which it is derived, unless we are prepared to allow that carbon is sometimes tervalent. Ethylene the substance differs from ethylene the radical in having its two carbons differently related; but it is difficult to see how to make a similar distinction in the case of Gomberg's substance.

In those other cases in which the point is not strictly determinable, only because the resulting substances are the simple substances themselves, it required but the recognition of molecular quantities to make it evident that these cases run parallel with the others. For, in all changes which can be satisfactorily followed out, the resulting or entering quantity of the simple substance is twice as great as that which can have come from, or gone to form the molecule of either of the compound substances. But if, so far as can be traced, a simple substance comes only half from one molecule of any of its compounds, none of these compounds can contain or be composed of simple substances. All simple substances, therefore, as well as all compound substances, enter into and come out from chemical changes as dual in all of them in origin and disappearance. Their colligative properties have been appealed to in order to confirm this observation, but with conflicting results, sometimes confirmatory of the chemical evidence, sometimes contradictory of it, and sometimes too complex for confident chemical interpretation.

I refer here more especially to Avogadro's proposition, which is in effect that equal volumes of gases are chemically equal or molecular. As in the case of Dalton's atomic theory, there is to be distinguished in this proposition what Avogadro really put forward as new from what he took for granted. Admitting, as was to him a matter of course, that gases have in equal volumes equal numbers of particles, he asserted that in the case of elementary substances these particles are not the atomic particles, but, as in the case of compound substances, particles compounded of these, which interact with the particles of other gases as chemically equal each to each. If now this proposition is divested of all hypothesis, all reference to the mechanical structure of gases, it becomes the law that equal volumes of gases at the same temperature and pressure, whether simple or compound, are almost exactly chemically equal quantities, and once in possession of this law we find nothing becomes clearer by assuming that equal volumes of different gases contain the same number of chemically equal particles. This law is, obviously, an advance upon Gay-Lussac's law similar to that of the chemical molecular theory upon the atomic theory of Dalton. Unfortunately, however, it does not hold good in the case of not a few simple substances, and it seems impossible from the chemical point of view, and consistently with the molecular theory, to admit that, because the gas-volume has only half the expected mass, the chemical molecule of sodium or mercury is not bipartite like that of hydrogen or oxygen, and chemically equal to either.

The dual constitution or chemically compound nature of the simple substances as thus established by the part they take in chemical interactions furnishes further evidence of the untenability of the belief that the molecule is chemically composed of two substances, or their substitutes, simpler than itself, when we consider that, were this true, there would be chemical union between two things perfectly alike, two portions of the same thing. This difficulty was, I believe, first raised by Berzelius, and has never been met. Physically, the matter is simple enough, if motion in the opposite direction is not counted as a difference between two masses. But this would be a non-elective union, whilst chemical union is elective.

The difficulty, insurmountable when made, does not arise when the fact is recognised that every chemically single substance, whether simple or compound, is, as a substance, one and without parts, and can never, therefore, be built up of or broken down into parts different from itself. One substance (as two molecules) or two substances change into two others or into two molecules of one, in an interaction which is instant, uninterrupted, and irresolvable into stages, where the interaction is single in character. But just as a body can be mentally analysed (as in the investigations of dynamics) into mass and motion, which apart are unknown, and as these again can each be conceived of as further divided, resolved, condensed, and otherwise qualified as centres of mass, compounded motions, and so forth, so the chemist is enabled mentally to find quantitatively defined this, that, and the other mark of the many chemical interactions which have or may have gone to bring it into existence, and will or may again have place in the possible forms of its dissolution into others. The two methyls in the constitution of ethane, about which we are quite certain, are not two things held together till some interaction sunders them in

the chemical dissolution of ethane, but the double mark of similarity between it and other methyl compounds in their chemical interactions. We cannot say that only one part of the ethane is methyl, or hydrogen, or carbon, but that part of its nature, of its constitution, is its behaviour as a methyl compound, or, again, as an ethyl compound; or, more comprehensively but less specifically, part of its constitution is its behaviour as a hydrocarbon, as a hydrogen and as a carbon compound. But these are different aspects of it, different relations of it, not differing parts of the one homogeneous substance.

With the laudable object of combating the prevalent notion that matter is something which is the basis or essence of a body, something acting as the medium of the manifestation of its forms of energy, a distinguished and most lucid writer on chemistry has, adequately perhaps for that object, represented a body as a compound of the various forms of energy subsisting together and cohering in certain proportions within the volume of the body. But this presentation of a subject as a cohesion or association of forms of energy is on the same footing as the presentation of ethane as consisting of two methyls bonded together, or two portions of carbon with six of hydrogen. It is compounding what cannot be had apart, what cannot be even conceived of as separate, so far as bodies are concerned. The analysis of bodies into manifestations of different properties are only mental operations. A moving body, a hot body, a green body, an explosive body, becomes by legitimate abstraction a phenomenon of motion, of heat, of colour or of light, or a chemical phenomenon as our needs require; but the body is there all the while, and its undivided and continuous existence is indispensable to the phenomenon. The body can be hotter or colder, but not that only—not that without other differences; red-hot iron is throughout a very different thing from cold iron, and ice differs widely from steam in most of its properties. A substance is no more composed of its properties or energies than it is composed of its so-called elements. It manifests its presence in a thousand and one ways more or less distinguishable; its properties are so to manifest itself. But no divisibility of itself while it remains itself can be thought of, no differentiation can be suggested, no nucleus with its superinduced properties can be traced.

It ought, therefore, to be possible to express all the particulars of chemical constitution without making any assumption as to substances having parts or structure. Of chemical constitution itself, I doubt whether there is to be found a definition which is not couched in language having reference to the minute mechanical structure of substances, notwithstanding the fact that all knowledge of their chemical constitution has come to us through observation of the properties of the substances themselves, and more particularly their relations in cases of double decomposition. Bearing in mind that all terms are relative, I think the chemical constitution of a substance may be defined as the resemblances shown by it in its chemical changes to other substances, often better known than it and taken as types, these resemblances being indicated and described usually by means of special nomenclature and notation. As this nomenclature and notation have been developed out of those designed to express chemical composition, it is well to point out that the notion of chemical constitution is independent of that of the latter, though clothed to some extent in its language and symbols.

The notions of radical and atom are so intimately related as to be often used indifferently, the one for the other. The radical ethylene is always an atom of ethylene, the radical nitrogen always an atom of nitrogen. Radical and atom are, in fact, the qualitative and quantitative aspects of the same thing. They are thus exactly parallel with substance and molecule. We can think of unquantified substance, and perhaps of unquantified radical, but in chemistry we never really want such conceptions; one of the many definitions of science is the quantification of phenomena, and in every chemical phenomenon the substances concerned are quantified as molecules. The quantification of radicals expressed by the atom is fundamentally the same in principle as that of substances, namely, that of chemical equality in interaction; but it may be better to say that it is dependent upon the quantification of substances as molecules.

In the interaction of double decomposition each substance by contact and union with the other develops and manifests a dual character by becoming distributed as the two new substances, with the consequence that each of these has certain properties the same as those of the one, and certain others the same as those of the second interacting substance. What is common in this way to one of the interacting and one of the resulting substances is a radical of these substances, of which there are evidently four in every double decomposition. These radicals of a single interaction are defined as whatever two parts of the powers of a substance to yield the simple substances of its chemical composition are, in certain interactions, continued separately from each other in the two new substances. But the pair of radicals developed in the various double decompositions of a substance being by no means always the same, one of the radicals of one pair must include in its composition part or all of one of those of another pair. Acetic acid has for one pair of radicals methyl and carboxyl, and for another pair acetyl and hydroxyl. Of these, carboxyl includes hydroxyl and acetyl includes methyl. Again, acetic acid yields the hydrogen and acetate radicals in one interaction, and hydroxyl and acetyl in another, so that in these cases the acetate radical includes acetyl and the hydroxyl includes the radical hydrogen. Now, what is common to carboxyl and acetyl and what is common to the acetate radical and hydroxyl are also treated as radicals, the one being known as carbonyl and the other as the radical oxygen. These are examples of what may be distinguished from the others as the polyvalent radicals. They are radicals of radicals, and therefore also radicals of substances. They may be defined as the common part of two or more other radicals. A single definition of all radicals can be given, but it is not instructive. A radical is any single power or any interdependent association of the powers of a substance to produce simple substances which continue in any product or series of successive products of its chemical change.

Before I leave the subject of the radical I wish to repeat that it is only when it is interacting that a substance shows a dual character or division, as it were, into parts or radicals, and that the duality it then shows is determined as much by the nature of the other substance as by his own. A substance is neither actually nor conceptually the sum of its radicals. The very fact of the difference of these in different interactions should be proof of this; though it only leads to its being taken to be at least the sum of its ultimate or simple radicals. If, however, it is not the sum of its proximate radicals, it is hard to see how it can be imagined to be that of the ultimate ones. In relation to its radicals, a substance must be held to present itself as any one of these for the purpose of investigation, and at the standpoint from which it is considered. It is then to the mind that particular radical, though also something else; just as snow is white and cold, yet also something else, for the moment unconsidered. Nor can the two products of an interaction be looked upon as themselves the sum in properties of the interacting substances. To a limited extent, and imperfectly, we can attach to a given radical certain of the properties common to its compounds; but it needs no greater insight than we have already to recognise that a substance cannot be what it is in one way, without being in that way greatly affected by what it is in another. This is now a recognised but not sufficiently considered point, and I therefore welcome those publications of Prof. Vorlaender, of Halle (who now honours this Section with his presence), in which he has been vigorously calling attention to the extent to which the properties of a substance, acid, basic, stable, and what not, depend as much as, if not more, upon the interrelations of the radicals than upon the radicals themselves.

One other thing I have to say about the radical, which is as to the spelling of the word. I plead for a return to the ending of the word radical with "al," now interdicted in the *Journal* of the Chemical Society. It seems appropriate to call the powers of a substance to behave chemically as it does, the roots or radical parts of its chemical nature, but it does not seem appropriate to call them radicles or rootlets. Americans and all other nationalities but our own use the original spelling.

I have put off too long, perhaps, all reference to the properties of very dilute aqueous solutions of salts, but I wished first to discuss the nature of the radical. The osmotic pressure and other dependent points which are particular in the behaviour of such solutions are in full accordance with the assumption that an electrolyte by dissolution in much water becomes a pair or a binary system of two interdiffused quasi-substances called "ions." These ions must differ from isolated substances in bearing equal and opposite quantities of electricity; in being each unknown apart from its fellow; and in having a composition not to be found in actual substances, though identical possibly with that which a radical would have were it a

substance. The ions can be indeed separated from each other, but not to continue as themselves, since in the act of separating they form ordinary substances, either by uniting with other ions, or by two molecules of ion becoming one molecule of substance. In the former way of separation the ions of two salts interact on mixing their solutions; in the other way, the ions become substances when their solution is placed in a galvanic circuit. In this mode of separation—by electrolysis, that is—the substances corresponding with the two ions, or else secondary products of their change, are produced, the one substance at the kathode and the other at the anode, while the solution away from the electrodes, but between them, remains for the time unaltered in composition. Along with this there occurs in many cases a phenomenon first recorded by Daniell, and afterwards investigated by Hittorf with such beautiful results. This consists in a greater fall taking place in the concentration of the salt solution close to one electrode than in the concentration of that close to the other, as though the ions were hydrate compounds, and that the one ion was a higher hydrate than the other. Until we know more of the nature of the ions themselves this phenomenon is most conveniently quantified on the hypothesis that the ions travel as molecular particles, but the discussion of this hypothesis is beside my present purpose.

The phenomena of ionisation or, in other words, the particular properties of dilute solutions of salts, belong evidently to a change unlike all other chemical changes. It is a polarised chemical change, in which the equivalent and complemental products of the interaction appear apart and at remote surfaces of the mass of decomposing salt solution. Two points which call for notice in connection with my present subject are that an ion is one of a pair of quantities commensurate with the quantity of the salt itself that is or would be in interaction; and that it is molecular in character and therefore to be regarded as a relative and wholly variable quantity.

Dalton's atoms were both the atoms and the molecules of present-day chemistry, but much more the latter than the former. Although the chemical atom can now be no more than a dependency of the molecule, it is commonly set up as the starting-point in chemical theory, and as having an independent existence as a quantity of the substance, while the molecule is represented as being a conjugation of atoms. But there cannot be two standards in reference to the same thing, and in molecular chemistry the atom must give way. As I have already had occasion to point out, the atom is of the radical, the molecule is of the substance.

The four radicals of a double decomposition are equal and chemically complementary. These chemically equal quantities of such radicals are atoms. The quantities of all other radicals are also atoms, but only those of proximate radicals, those of a single interaction, are equal. Similarly, the quantities of the four substances of a single interaction are all equal and are molecules, but the quantities of substances are not equal in other interactions. These others are treated as the simultaneous occurrence of two or more single interactions, which they can always be represented and sometimes demonstrated to be. Calcium hydroxide and hydrogen sulphide give calcium hydrosulphide and water by two single interactions together, which in this case can be easily distinguished, since the calcium hydroxide will also interact with only half as much hydrogen sulphide to form the insoluble crystalline calcium hydroxyhydrosulphide and half as much water as before; this calcium salt will then interact with as much more hydrogen sulphide as went to form it, and produce the very soluble crystalline calcium hydrosulphide. Or the calcium hydrosulphide and as much calcium hydroxide as yielded it will readily interact to form twice as much as the first-obtained quantity of calcium hydroxyhydrosulphide. Thirdly, the calcium hydrosulphide and half as much water as was formed with it from calcium hydroxide readily interact to produce calcium hydroxyhydrosulphide, and half as much hydrogen sulphide as was needed to form the hydrosulphide. Therefore, and on other grounds, we say and know that one molecule of calcium hydroxide and two molecules of hydrogen sulphide give one molecule of calcium hydrosulphide and two molecules of water. This is, of course, only the law of multiple proportions introduced into chemical interactions. The expression "two or more molecules of a substance" has a meaning only as indicating the number of simultaneous or successive single interactions which have led to the conversion of certain substances into others.

Now a similar but complementary state of things meets us in the case of radicals. Instead of the coefficients of molecules, necessitated by having to consider many chemical changes as being cases of two or more single interactions occurring together, there are the valency coefficients of the polyvalent radicals, called out also by such a compound interaction. Thus, in the above case, whilst the single interaction between hydrogen sulphide and calcium hydroxide shows calciumhydroxyl as one of the radicals, the succeeding interaction between the calcium hydroxyhydrosulphide and more hydrogen sulphide shows the radical calciumhydrosulphuryl, and the common part of these two radicals is the bivalent radical, calcium. It will be evident that to give the atom of the calcium radical as bivalent is a statement reciprocal or complementary to that of giving two molecules of hydrogen sulphide as interacting with one of calcium hydroxide. Chemical equality remains still the measure of the atom, but that, in complex changes, whereas the number of molecules of one substance marks the number of single interactions, the valency number of the atom marks the same thing for the radical. It is a matter of valency, and not otherwise a matter of the atom. The radical calcium is never actively bivalent in a single interaction; in other words, it is never equal to two atoms of hydrogen. As a simple radical it does not take part in such an interaction; but it does do so as a radical of radicals, such as calciumhydroxyl and calciumhydrosulphuryl, and then has the same measure as—is equal in exchange to—the atom of hydrogen, though carrying with it of necessity other radicals, a thing the hydrogen radical never does or can do. To take another example; when acetamide is formed from acetic acid, the nitrogen of the amidogen and the oxygen of the hydroxyl are equal in exchange, but because of their valencies the one carries with it two atoms and the other one atom of hydrogen. This is no matter of merely academic contention, for upon its recognition rests the doctrine of valency itself.

The quantity of the radical is the only proper and sufficient definition of the atom, whether the radical be that of a single interaction, or a radical of radicals, that is, a polyvalent radical. The atom is, therefore, the quantified power of a substance, as the compound of the radical, to produce other compounds of the radical, including its compound with itself, where that is possible. As with the molecule of a substance, so with the atom of the radical, it is of no fixed magnitude, and may weigh a kilogram just as well as only a milligram or something much less. Being a relative quantity and nothing by itself, of its indivisibility there is nothing to be said outside its definition; whilst, as to its being the smallest relative quantity interchanging in an interaction, it had only thus to be defined when there was uncertainty as to the molecule and the single interaction.

It has been impossible for me to discuss the nature of the radical and the atom without referring to valency, but it is itself a subject of such importance as to need special consideration. It does not seem right to me to say even the little I can say about valency without naming with the respect they deserve from us the distinguished chemists who laid the foundations of the doctrine and developed it: Williamson, Odling, Wurtz, Edward Frankland and Kekulé. I had the good fortune to be in the same laboratory as, and then intimate with, Kekulé when, in 1854, he was working out the bivalency of sulphur and oxygen by his investigation of thioacetic acid, some time, that is, before he had thought out the benzene ring and the valency of carbon.

Only when, as is usual, propositions are made in which a separate and independent existence, with valency as a property, is imputed to a radical does the question, as to what valency is, present any difficulty. Approaching it from the side of the molecule and of double decomposition, and therefore from the experimental side instead of from that of the radical itself, as is customary, valency presents itself as being the number of single interactions necessary in order to have a certain radical occur, first as that of one substance, and then as that of another which has no other radical in common with the first substance. That ammonia possesses one atom of the radical nitrogen and three atoms of the radical hydrogen, and that the nitrogen radical is tervalent and the hydrogen radical univalent, are statements mutually based upon facts such as the following. Potassium nitrilosulphate, which contains nitrogen but no hydrogen, is converted by water in a sharply defined single interaction, into potassium hydrogen sulphate, and into potassium imidosulphate, a substance which contains all the nitrogen along now with hydrogen. This salt passes, also sharply and by a single inter-

action with water, into as much more sulphate along now with potassium amidosulphate, which latter substance contains all the nitrogen and twice as much hydrogen as belonged to the imidosulphate. Lastly, the amidosulphate interacting with water gives a third quantity of potassium sulphate, equal to the last, and also ammonia, having all the nitrogen of the nitrilosulphate started with, three times as much hydrogen as the imidosulphate, and nothing else. That is to say, the nitrilosulphate and the ammonia have no other radical than the nitrogen the same, while three single interactions have been necessary to separate in this way the nitrogen radical from the three atoms of the potassiumsulphonyl radical. Therefore the nitrogen radical is tervalent and its quantity is the atom. Again, there are three atoms of the univalent hydrogen radical in the ammonia molecule, because in each of the three interactions an equal quantity of this radical is brought in from water. Ammonia shows only one pair of radicals, behaving, so far as its own interactions go, exclusively as a compound of amidogen and hydrogen, and these radicals are referred to as united or bound together in being ammonia. It is only the interactions of its derivatives, primary, secondary and tertiary, that are indicated by treating the amidogen as ultimately nitrogen and two hydrogen radicals. But this involves the consideration of all three hydrogens as bound to the nitrogen; and it becomes, therefore, of vital importance to bear in mind that the hydrogen radical, proper to the ammonia itself, is bound to a nitrogen radical which carries also bound to it two other hydrogen radicals.

Chemical formulæ still remain to be considered. They are symbolisations of deductions from experimentally ascertained facts, and are independent of the interpretation commonly given to them as referring to the minute differentiated structure of substances. A chemical equation expresses a chemical change quantitatively by means of chemical formulæ which are molecular. In a case of double decomposition, therefore, there are four formulæ; but when two or more such interactions are expressed in one equation, because they occur together, the formulæ of transition-substances do not appear, and then numerals before formulæ tell the number of interactions in which separate molecules of the substance have taken part. A formula represents the relative interacting quantity or molecule of a substance, while the single symbols composing it stand each for an atom of the radical of a certain simple substance as possessed by the substance formulated. The connecting lines and dots, and certain collocations of the symbols, indicate the association of the simple radicals as compound radicals in different interactions.

What is symbolised by position formulæ, and indeed by the formula altogether, are the chemical activities and abilities of the substance and its derivatives, and their analogies with those of other substances. When not in interaction, a substance has no constitution and no formula. In is certainly not on any experimental grounds that it can be regarded as some spatial arrangement of unlike parts. To take the simplest case; if we start with sodium hydroxide and symbolise its molecule by some mark, such as X to begin with, the interaction of the substance with an acid leads us to replace the X by two symbols and a connecting mark. One of these will be Na for the sodium radical; let the second be Z for the other radical, and let a dot or stroke be placed between the symbols to mark them as those of a pair of radicals in interaction. In other interactions, such as that with melted potassium acetate, we find need for a new pair of symbols, one being H for the hydrogen radical, while the other may be Q. But it is easy to decompose two molecules of sodium hydroxide in one operation into molecules of sodium, hydrogen and oxygen, from which fact we learn that Z is replaceable by the double symbol O H, and Q by O-Na. Thus, Na-Z and H-Q became equally Na-O-H, which records the ultimate radicals of sodium hydroxide, together with all its interactions, immediate and remote. But it does this with no more implication of spatially placed and tied parts than is made by expressing the measured flow of time by a straight line, or than is to be found in t^2 seconds of time, or in c^3 as the third power of a number, unless we specifically condition this symbol as stereometric. A formula is not to be read—on experimental grounds, I mean—as a symbol of parts juxtaposed and joined on, and should be regarded as an intricate but legible monogram telling the chemical nature of the substance. Every symbol in it is to call to mind a phase of the chemical activity of the substance or of its derivatives, a phase that may be for the time as the substance itself to the investigator, just as a pigment substance becomes only a red or a white to the painter. For example, salt is often nothing more than its chlorine phase to the chemist when he wants only a soluble chloride; whether it is of potassium, sodium or ammonium, then, matters not to him.

The double linking of the carbons in ethylene is a symbolised expression of facts without reference to hypothesis. The two carbon radicals of ethane or of alcohol behave together just as does the single carbon of methane or the nitrogen of ammonia in being, but with a valency of six, continued to other compounds devoid of all the other radicals of the ethane or alcohol —that is, of the hydroxyl and the hydrogens. The quadrivalency of each carbon is made up by the interaction necessary to dissociate or to bring together the two methyls, which counts as a unit of valency to each carbon. Ethyl hydrogen sulphate decomposes into sulphuric acid and ethylene, the hydrogensulphate radical with a hydrogen radical becomes the acid as the one product, while the methylene radicals again pair off as the two methyls had done when ethane was formed, thus producing the non-saturated substance, ethylene. Since there is a perchlorethylene, the second linking mark falls between the two carbons; and when ethylene passes back to an ethane compound two units of valency are displayed by it without the carbons becoming dissociated.

Position formulæ of isomerides, such as those of propyl alcohol and acetone, present no difficulty, because they are interpreted as the expressions of unlike double decompositions. It is not unfrequently the case that no constitutional or structural formula can be given to a substance which shall express all the pairs of radicals possible in its interactions, of which the best-studied example is that of ethyl acetoacetate. This state of things, known as tautomery, admits of no other interpretation than that there are really two substances existent, of which one only is known, the other or so-called "pseudoform" requiring the assumption of its existence as a transition-substance only. The notion of the shifting hydrogen radical is but the hypothetical way of viewing the intervention of the intramolecular change by which the substance becomes its "pseudoform."

The cyclic formula of benzene expresses the fact that, unlike a fatty hydrocarbon, benzene shows but one pair of interaction radicals, hydrogen and phenyl. The "ortho-," "meta-" and "para-" positions in benzene derivatives are only expressions of facts of "position" isomerism, such as those pertaining to other non-saturated compounds, but more complex to unravel and more varied and interesting. It is doubtful whether the Kekulé ring does not remain as efficient a symbol as any stereographic substitute yet proposed for it; but it itself is purely a symbol of chemical interactions, and has no spatial significance other than what may be put into it by convention. "Adjacent," "opposite" and the like have only application literally to the arrangement of the symbols; but if the symbolisation is perfect the "opposite" carbons will, as a matter of course, always indicate the same point concerning the chemical interactions.

Whether the chemical formulæ for the lactic acids are better arranged in a plane or as a tetrahedron is to be decided by the facts concerning these and other asymmetric carbon compounds, the object being to symbolise or formulate as distinct and complementary in certain physical properties, but alike in their chemical interactions, two isometric substances, simultaneously formed in molecular quantities. Enantiomorphous arrangements of the respective formulæ of dextro- and lævo-lactic acids fully meet the case, but the facts are in no way explained by these formulæ. In the enantiomorphously related hemihedral crystals of the corresponding salts of the dextro- and lævo-acids, and in their opposite rotatory effect in solution upon the plane of polarised light, we recognise something like a torsioned state of the whole homogeneous substance, something to be accounted for by peculiarity of chemical origin, but not something made more intelligible by any imagined arrangement of unlike parts. It is possible to give an account of the chemical facts without making reference to mechanical structure, and then to reason about them somewhat in the following way: Given the case of a substance doubly equipped with the power to take part in a certain interaction, and considering that the exercise of the power can only be single, and that it cannot be made without affecting and transforming, or perhaps nullifying, the second equipment with power, predict what will happen. That is the prediction called for concerning any interaction which generates an asymmetric carbon compound. The result could never have been predicted; yet how natural and beautiful it is when it comes to us through

experiment enlightened by the genius of Pasteur, Le Bel and Van 't Hoff! That answer is that a twinned substance results, one indeed in most respects and chemically, but two in certain physical properties, characterised by presenting phenomena as of equal and opposite strains, a polarised pair of substances, in fact. What I mean by the double equipment with power is, of course, the pair of identically related and self-identical radicals, or the bivalency of one radical wholly and directly associated with the carbon radical. The case of the oxygen radical of aldehyde is that of the bivalent radical; the other case is that of the two carboxyl radicals of hydroxytartronic acid, or that of the two methylene hydrogen radicals of alcohol which these carboxyls have replaced. The tetrahedral formula with its reflected form admirably symbolises the case of enantiomorphously related pairs of substances. But no light whatever is thrown upon the nature of this pairing by the tetrahedron model; its value depends upon the fact that as a symbol it so fully matches the constitution of the substances.

Here I bring my summary of chemical theory and its formulation without hypothesis to a conclusion, hoping that, to some extent, I may have impressed you with the fact that the exposition of even advanced chemistry, in its symbolic, equally as in its ordinary language and nomenclature, is independent of any hypothesis as to the mechanically and chemically differentiated structure of substances, and that chemistry can be studied and still further developed without reference to such a structure. I have asked for few or no reforms in the use of either terms or symbols, my point having been only to press for a consideration and discussion of the doctrines of chemistry and the great atomic theory itself as something concerned exclusively with experimental chemical facts.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY LIEUT.-GENERAL CHARLES ALEXANDER McMAHON, F.R.S., F.G.S., PRESIDENT OF THE SECTION.

Rock Metamorphism.

I WISH to offer some observations to-day on some aspects of rock metamorphism; and as this is a complex subject, and the time at my disposal is brief, I purpose to deal with it in simple language, and to avoid as far as possible all petrological technicalities.

A short description of a granite in the Satlej Valley of the Himalayas will, I think, introduce us by a short cut to the consideration of "contact metamorphism," an important branch of the subject under consideration.

The granite I allude to is an intruder in the normal gneissose-granite of the Himalayas, and cuts through it at right angles to its foliation.

The intruder, which is some yards wide, did not rise through a simple crack or fissure, for its passage upwards was interrupted by a sheet of dark intrusive diorite, older than itself, which ran, roughly speaking, parallel to the foliation of the gneissose-granite.

This sheet of diorite offered considerable resistance to the rising granite.

The granite zigzagged backwards and forwards across the diorite and ran along its edges for fifty yards or more, converting it into a mica trap.

It then tore itself away and continued its upward course. The granite I am describing was in a molten or fluid condition at the time of its eruption, as I hope to show in my subsequent remarks.

I may pause here, however, to consider in passing what was the probable temperature reached by a granite such as that above described.

The question is one of very great difficulty, as we know so little about the plutonic conditions of igneous rocks, and can only arrive at an answer to our question by indirect evidence.

The melting point of quartz ranges from 1425° to 1450° C., but the fusion point of granite need not necessarily be as high as this, inasmuch as the presence of water at high temperature materially lowers the melting or solution point.

The fusion point of the other constituents of granite may here be mentioned: that of orthoclase ranges from 1164° to 1168°; microcline, 1169°; albite, 1172°; augite and hornblende, 1188° to 1200°; apatite, 1221°. Zircon, which is commonly found in granites, and is one of the first minerals to separate out of the magma, is shown by Ralph Cusack to have probably a melting point of 1760°: whilst topaz, a not uncommon mineral in granite, is infusible up to the melting point of platinum, namely, 1770° C.

If we consider, therefore, the melting points of the mineral constituents of granite, we can hardly avoid the conclusion that for the magma to have attained perfect fluidity it must have reached a temperature of at least 1200° C.

Vernadsky has shown that kyanite is transformed into sillimanite, a well-known product of contact-metamorphism at a temperature of 1320 to 1380°.

If rocks in contact with granitic masses have been raised to this temperature, it follows that the granite itself must have been still more heated. Vernadsky's observations have been relied on by Mr. George Barrow in his well-known paper "On an Intrusion of Muscovite-biotite Gneiss" in the S.E. Highlands of Scotland to account for the presence of sillimanite in the inner zone of metamorphism between the kyanite schists and the granite, and he considered that the temperature attained by the "central masses of the Highland rocks" was probably higher than the figures indicated by Vernadsky.

Bearing all considerations in mind, including the influence of water and alkali in reducing, and of pressure in raising, the melting point, I think we may safely infer that granites, such as the Himalayan granite alluded to above, must have been raised at plutonic depth to a temperature midway between red and white heat, that is to say, to at least 1200° C.

To return to the granite of the Satlej Valley under consideration, I wish to draw attention to its condition just before crystallisation commenced.

A study of the mineral beryl will, it seems to me, throw light on this point.

Beryl is an important accessory mineral of the granite under description. It is clearly an original mineral, and it is material to note that it was the first mineral to crystallise out of the magma of the Satlej granite. This is shown by several circumstances.

In the first place the beryl preserved its perfect crystallographic shape, showing that its molecules during the entire period of crystallisation possessed comparative freedom of motion, and were not interfered with or molested by other solid minerals. In the second place all the essential minerals of the granite when they subsequently crystallised out of the magma were deposited on the crystals of beryl. I have specimens of the granite showing crystals of beryl enclosed in felspar, in muscovite and in quartz.

The beryl, therefore, having been the first mineral to crystallise, the examination of thin slices of it under the microscope ought to give us a clue to the condition of the magma at the time the beryl was formed.

I have made such an examination, and I find that the beryl is crowded with liquid and gas cavities, the former containing movable bubbles and deposited crystals as well as water.

The bubbles are of substantial size relative to the area of the cavities, showing that the water suffered considerable contraction after it was sealed up in the beryl.

Scrope long ago suggested that the fluidity of lavas below the melting point was due chiefly to the water they contained, and attributed the liquidity of granite to the same cause.

Scrope, however, in ascribing the mobility of an igneous rock to the presence of water, seems to have had regard principally or wholly to its mechanical action in furnishing an elastic medium in the interstices between the crystals or grains of the rock. He observes that a lava consists "of more or less granular or crystalline matter, containing minute quantities of either red-hot water, or steam in a state of extreme condensation, and consequent tension, disseminated interstitially among the crystals or granules, so as to communicate a certain mobility to them, and an imperfect liquidity to the compound itself," and he quotes Scheerer and Delesse, both of whom assert that water exists in mechanical combination with all crystalline rocks, "its minute molecules being intercalated between the crystals."

Nowadays one would attribute the liquidity of an igneous rock not so much to the mechanical action of the water present in it as to the combination of the water with the mineral contents of the lava, producing a state of solution.

Sorby's investigations supported Scrope's observations, for he proved that the liquid contained in the inclusions in granite is

water, and showed that it was caught up during the formation of the crystals, "and was not introduced subsequent to the consolidation of the rock."

The water now contained in cavities in the beryl was probably held in solution by the constituents of that mineral at the time of its formation, and as it cooled down the water separated from the substance of the beryl and formed the cavities in which we now find it imprisoned.

If this be so, it follows that when the beryl crystallised out of the magma, the latter was in a fluid condition, and held a considerable amount of heated water in solution. The temperature of the magma must have been above that of red heat, and the potential energy of the water held in a fluid state by pressure must have been great. When therefore in the course of the earth movements which accompany or in some cases are caused by the intrusion of eruptive igneous masses, pressure was temporarily relieved by the rupture and faulting of rocks, the superheated water contained in the magma would be ready to flash into steam with almost explosive violence.

It must also be borne in mind that water under great pressure, at or above a red heat, has a powerfully solvent action on most minerals, even on so refractory a mineral as quartz. When therefore granite in the molten and fluid condition of the Satlej granite was erupted along a line of faulting, fissure, or weakness, the superheated water or steam, bearing with it much mineral matter in solution, must have acted with great chemical energy on the rocks into which it was intruded.

I have spoken of water carrying mineral matter in solution, and of a magma carrying water in solution. These two conditions may rapidly succeed each other under varying conditions of temperature and pressure. To use the words of Van Hise, "under sufficient pressure and at a high temperature there are all gradations between heated waters containing mineral material in solution and a magma containing water in solution."

The condition of the beryl crystals, crowded as they are with liquid cavities, shows how high a proportion of superheated water was contained in the fluid granite magma at the time of their formation.

Sorby estimated that the fluid cavities in the quartz of granites sometimes amount to more than ten thousand millions to the cubic inch. As quartz, however, is usually the last mineral of a granite to consolidate, it may be thought that the water contained in it is a residuum left by the felspar and muscovite on their separation from the magma; but the case of the beryl above quoted shows clearly that the amount of water diffused through the magma before the mica, felspar and quartz began to consolidate must have been very considerable. The amount of water held in solution by a granite, during the time of its aqueo-igneous fusion, cannot be estimated by the amount of water given in the analysis of consolidated and dried hand-specimens of that rock. A considerable proportion of this liquid must necessarily have been lost during the gradual cooling of the rock, and in the course of its intrusion into neighbouring sedimentary strata as sheets, dykes and veins. Sorby, as the result of other lines of investigation, came to the conclusion that the amount of water present in granite, though limited, is considerable.

We must now turn for a few minutes to consider the important question of the porosity of minerals, and their permeability by heated water and gas at high pressure.

The fact that solid substances are built up of molecules having interstitial spaces between them hardly needs demonstration nowadays.

But have we all quite realised that the molecules of rock-forming minerals and crystals are not inert particles of matter, but that they vibrate or revolve or are endowed with other orderly movement that may be likened to the motion of the planets round the sun?

Far, far away in space the solar system would, to an eye formed like our own, in all probability present a nebulous appearance, because the eye would not be able to see the individual members of our system.

So, too, the molecules of which crystals are built up may have their appropriate motions, but we cannot see them with the eyes of sense because the molecules are beyond the highest powers of the microscope.

We can, however, I think, perceive them with the eye of the scientific imagination; and the hypothesis that the molecules of minerals are separated from each other by intermolecular spaces, and have their modes of motion, seems essential to the comprehension of rock metamorphism.

The important experiments of Sir W. Roberts-Austen on the diffusion of gold in pure lead throw considerable light on this subject.

Disks of solid gold were held against the bases of cylinders of lead by clamps, and were kept in an upright position at the ordinary temperature for four years. At the end of this time it was found that the gold had diffused upwards in the solid lead, for a distance of 7·65 mm., in sufficient quantity to be detected by the ordinary methods adopted by assayers. Traces of gold were found still higher.

When a column of molten lead, 16 cm. high, was placed above solid gold and kept at a mean temperature of 492° C., that is to say, at 166° above the melting point of lead, but 569·7° below that of gold, the gold diffused in considerable amount, to the top of the lead column, in a single day.

Sir W. Roberts-Austen's experiments, above alluded to, demonstrate that even such metals as gold, whose melting point is as high as 1061·7° C., exhibit a measurable amount of kinetic energy at the ordinary temperature and pressure. Great results may no doubt be brought about at ordinary temperatures and pressures, when time, as in the laboratory of nature, is practically unlimited; nevertheless the importance of high temperature and high pressure, in operations connected with metamorphism, can hardly be overrated.

Not only does a rise in temperature increase the energy of the chemical actions and reactions which produce the mineralogical changes embraced by the term metamorphism, but it increases the porosity of minerals and facilitates the passage of liquids and gases through their pores.

The cohesion of molecules is lessened, the amplitudes of their vibrations, rotatory or other movements, are increased, and a passage is opened for the advance of chemical materials into the heart of the crystal.

Increase of temperature thus not only throws open the doors of the mineral fortress attacked, but gives enhanced energy to the invaders. The fact that the mineral components of a rock are, under conditions of heat and pressure practically porous to heated water, laden with chemical reagents in solution, is frequently brought home to the mind of the petrologist in a very tangible way. We sometimes observe, for instance, that metamorphic changes begin at the heart of a crystal, and leave the peripheral portions of it fresh and unaltered.

In such cases the chemical agents of change have evidently passed freely through the outer parts of the crystal, and have by preference selected its internal parts for attack.

In order to explain clearly how this remarkable result takes place, in the cases referred to, it will be necessary to diverge for a few minutes to consider another branch of our subject. It is difficult, if not impossible, to lay down any hard-and-fast rule of universal application, because the conditions under which igneous rocks crystallise vary with temperature, pressure, the relative proportion of constituents and other local causes, and these variations in the conditions may materially affect the results; but I think the rule that minerals crystallise out of a molten magma in the order of their basicity is of very frequent if not of absolutely general application. This rule also governs the growth of individual crystals, especially those that exhibit what is known as zonal structure. Take, for instance, the felspars of an igneous rock. A gradual passage may frequently be traced by the petrologist from one species of felspar at the heart of a crystal to another distinct species at its periphery. Sometimes a crystal is made up of more than two species, which shade more or less gradually into each other. In accordance with the rule laid down above, the more basic species formed first; then, as the percentage of the bases left in the magma gradually decreased, owing to the first formed crystals having taken a lion's share of the available bases, the felspars that formed later became gradually more and more acid in composition. Thus a large felspar of slow and gradual growth may be composed of several zones, each zone being successively less basic and more acid than that upon which it crystallised, each successive zone thus possessing slightly different physical properties from the one that formed before it. These statements are capable of proof. When sections of felspar, such as occur in thin slices of igneous rock, are examined under the microscope in polarised light, petrologists can distinguish one species from the other—when the direction in which the sections were cut is approximately known

—by measuring the angles at which they extinguish from the twinning or the pinacoidal plane.

This is not mere theory. Each species of felspar has its own angle of extinction and its own index of refraction. The determination of these two factors enables a petrologist to prove optically the change in composition; or, in other words, the change in species which has taken place in the successive zones, during the gradual growth of a large zonal felspar.

Another general rule must now be mentioned. I think it may safely be asserted as a broad rule that the different species of felspars are attackable by the chemical reagents which make themselves felt in metamorphic action, in the order of their basicity; that is to say, the more basic felspars are more easily attacked than the acid ones. When we bear in mind the facts stated above, we shall, I think, be able to see clearly how it is that the peripheral portions of large felspars in igneous rocks sometimes escape alteration, whilst the cores of these crystals are converted into secondary minerals, such as chlorite, silvery mica, zoisite, epidote, kaolin, steatite, saussurite, calcite and scapolite.

The chemical reagents flowing in solution through the pores of the felspars, pass by the more acid and refractory species and devote their energies to the more susceptible basic species entombed at the heart of the zonal crystals.

The point I wish to enforce most strongly is that the phenomenon above described, namely, the formation of secondary metamorphic minerals in the interior of a crystal, combined with the comparative immunity to change of the external portions, shows that the agents which brought about chemical changes at the core of the crystal flowed freely through its unaltered peripheral portions.

But some may ask whether the chemical agents referred to may not have gained access to the heart of a crystal by a crack. I answer that a crack is a coarse and tangible object that looms large under the microscope. A crack in a mineral liable to metamorphic action, through which chemical reagents have flowed, could not escape detection. The finest crack through a homogeneous mineral, such as, for instance, an olivine, can be readily seen, not only by the small canal worn by the corrosive action of the chemical agents that flowed through it, but by the alteration set up in the mineral along the whole course of the canal.

I have a thin slice from a beautifully fresh olivine contained in one of the lavas of Vesuvius collected by myself. A volcanic explosion or other cause, operating after the crystallisation of the olivine, produced a very fine crack in the mineral through which water, charged with chemical reagents, subsequently flowed. The crack, though of microscopic width, is filled with serpentine, and on both margins fibrous serpentine has been formed at the expense of the parent olivine, and constitutes a fibrous band on both sides of the crack throughout its entire length, the direction of the fibres being at right angles to the crack.

The rest of the olivine is of virgin purity and polarises in the most brilliant colours, contrasting strongly with the serpentine.

In this case it is clear that the chemical reagents, through free to flow along the crack, had commenced to extend beyond its walls, encouraged thereto by the porosity of the olivine itself. But how different is this case from those in which the entrance of the chemical agents had not been facilitated by a crack. In the case above described, the chemical changes set up were limited to the borders of the crack, and even had they gradually extended in the course of time to the whole of the olivine, the original canal by which the chemical reagents had gained access to the crystal would have remained to tell its tale, and exhibit along its course the banks of iron oxide thrown down by the chemical navvies that had excavated it.

Cracks save time as roads and canals do, but they leave behind them evidence of their former existence. In order to understand fully how rocks and minerals are so completely open to the attacks of chemical reagents, which penetrate to and produce chemical and mineralogical changes at the very hearts of minerals, we must fully realise how completely porous rocks and minerals are, to the heated liquids which carry these reagents with them in solution. Heat, as before stated, not only increases chemical energy, but destroys more or less completely the cohesion between molecules, and increases the amplitude of the vibrations, or other motions of the molecules, and consequently facilitates the entrance of liquids and gases into the pores of minerals, and their complete permeation by these powerful agents of change. Thus far we have been chiefly concerned with some of the principles underlying the branch of our subject embraced by the term contact metamorphism, which implies operations conducted at considerable depths below the surface of the ground, under conditions of heat and pressure.

We must now consider very briefly changes produced at or near the surface by the agency of water, or, as Bischof in his well-known work termed it, metamorphism in the "wet way."

No hard-and-fast line, however, can be drawn between the two classes of operations, as the one gradually shades by fine gradations into the other. At one end of the scale we have high pressure and high temperature, and a fluid igneous magma holding water in solution, above a red heat, and giving up heated water or vapour charged with salts to the rocks in contact with it.

Passing to the other end of the scale through diminishing temperatures and pressures, we reach a condition in which the water circulating through the rocks at ordinary pressure and temperature is more abundant in amount, and holds acids and salts in solution, capable of setting up important chemical reactions in the rocks and minerals to which it gains access.

In the case of surface operations, moreover, the metamorphic agents—water, acids, salts—are being constantly renewed. Conditions differing as widely as the conditions at the extreme ends of our scale do not yield, however, precisely the same results. In both metamorphic change goes on with more or less briskness, but the products are different. Some minerals require great heat and great pressure for their production, and such minerals are never formed by any surface process of weathering. For instance, the temperature reached determines whether titanium dioxide crystallises as rutile, or in one of its other two forms, rutile requiring a temperature of more than 1000° C., and being the only form of titanium dioxide "stable at a high temperature."

Temperature also seems to determine whether the silicate of alumina crystallises as andalusite, kyanite or sillimanite, the two former being transformed into the latter, at a temperature of 1320° C. to 1380° C.

On the other hand, some minerals require little heat for their formation, and are readily produced by metamorphic changes in the "wet way."

There seems to be some correspondence between the melting point of minerals and their density; thus in the case of eleven minerals produced by contact metamorphism, whose average specific gravity ranges from 3·06 to 4·03, I find that their melting point ranges from 954° to above 1770° C., high temperature and high pressure (a concomitant of plutonic conditions) appearing to be factors in the production of high specific gravity in minerals.

The genesis of individual species of minerals is a fascinating study, but the subject is too large to enter upon here.

Water gains access to rocks in several ways. It falls as rain; it rises from hidden depths; it leaks from the sea into horizontal beds or into strata dipping away from it; and it penetrates through faults and fissures. Rain in its descent takes up from the air oxygen, nitrogen, carbonic acid, and in some cases small amounts of nitric acid.

It is thus in itself a powerful solvent and potent agent in producing chemical change.

In its passage through the surface soil it dissolves humic and other organic acids, the products of vegetable decay, which add greatly to its solvent power and enable it to break up many silicates and to dissolve even silica.

By the time the rain-water reaches the solid rocks below the surface soil, it has become a very active agent in producing chemical change in them. It is by such agents, persistently applied during long periods of time, that large areas of ultrabasic igneous rocks have been altered into serpentine.

Hot springs are a well-known instance of water rising in considerable quantity from plutonic depths. They are known to occur in the plains of India, and are especially abundant in the Himalayas. I visited two very interesting ones at Suni, in the bed of the Satlej River, west of Simla. These springs rise apparently under the very bed of the river, and come to the surface on both banks within a yard or two of the rushing water of the Satlej. When I visited the springs they had a temperature of 130° F., and contrasted strongly with the cold water of the river flowing past them, which had descended from high Himalayan glaciers and had a temperature of 49° F.

The native nhabitants of neighbouring villages told me that

the hot springs always appear at the very edge of the river, whatever may be the height of its waters during drought or flood. The statement is probably true, for I think the springs well up from below through the walls of a fault that traverses the bed of the Satlej at a high angle to its course, and the springs thus come to the surface on both its banks.

The metamorphic influence of these springs on the rocks in this locality has been very powerful. The ancient volcanic rocks there exposed have, for some distance up the river, been altered by aqueous agents almost out of recognition. The original structural characters of these lavas have been almost completely broken down and an amorphous substance substituted for the crystals and minerals of which they were originally composed.

This result shows that the crystals and minerals of these old lavas must, for all practical purposes, have been completely porous to the aqueous agents brought to bear on them.

The general transmutation of one mineral into another by the action of heated water holding mineral agents in solution, aided by heat and pressure, may take place in a variety of ways. Some of these processes are simple, but others are highly complex. Many are the results of a single operation, others of a series of changes, some of which prepare the way for those that follow.

In some cases the change may be brought about by the removal, in whole or in part, of one or more of the essential constituents of a mineral, whereby the relative proportions and mutual relations of those that remain are altered, as the following examples will show.

By loss of water limonite passes into hæmatite, and opal into crystalline quartz. Dyscrasite, by loss of antimony, passes into native silver, and pyroxene, by the removal of its lime and iron, is changed into talc. Simple oxidation or the absorption of oxygen by a mineral is responsible for another class of changes, as in the conversion of zinc blende into goslarite, and antimony into valentinite.

The loss of one or more of the ingredients, concurrently with the introduction of one or more new ones, causes many metamorphic changes, as in the conversion of marcasite into magnetite, of witherite into barite, and of azurite into malachite.

The well-known conversion of a peridotite into serpentine is a case in point. Here, part of the iron and magnesia is removed from the olivine, and water is introduced. A simple process like this, brought about by the percolation of surface waters through an igneous rock, is sufficient to transform considerable areas of rock masses into serpentine, as has been the case in parts of Cornwall.

Some metamorphic processes are more complex than those alluded to above, but Nature has unlimited time at her disposal, and is able to manufacture potent chemical reagents as her processes proceed. For instance, the sulphides of various metals of common occurrence in rocks, most of which, with the exception of those of the alkaline metals, are insoluble in water, by taking up oxygen pass into sulphates, most of which are soluble in that liquid at the ordinary temperature.

These sulphates are readily carried away in solution, and become potent factors of change in rocks through which water charged with these salts flows. Again, carbon dioxide, so abundant in percolating water, decomposes minerals containing lime or alkali, and removes them as soluble carbonates to effect powerful chemical reactions elsewhere.

I must pass over the subjects of paramorphism and pseudomorphism, as the limited time at my disposal does not permit me to enter upon these subjects.

In the above sketch I have contented myself with a brief discussion of some of the leading principles that seem to me to underlie contact action and metamorphism in the wet way, because I venture to think that, if we really understand these two divisions of our inquiry, it will be unnecessary on the present occasion to enlarge on other branches of our subject.

Take, for instance, what is commonly called dynamic metamorphism. The main factors in this kind of metamorphism are the folding, crumpling, crushing and shearing of rocks by earth movements, especially during the upheaval of mountains.

But these dynamic forces are potent factors in the development of heat.

In the case, therefore, of dynamic metamorphism, as in contact metamorphism, pressure and heat are the main factors acting in conjunction with the water shut up in or circulating through a rock. If we understand how these factors operate and produce the results we see in cases of contact metamorphism, we shall not fail to understand their action in a case of dynamic metamorphism.

These observations also apply to regional metamorphism; that is to say, to metamorphism produced in rocks at great depth, by being brought within the influence of the interior heat of the earth. The action of heat in increasing molecular motion and kinetic energy is well understood nowadays, and so long as we get heat it seems to me immaterial how heat is generated in rocks subject to metamorphic action.

In the above sketch I have intentionally omitted to enter into the details of chemical and mineralogical action that have brought about individual cases of metamorphic change.

Volumes would be required to do justice to so complex a subject, and the details would, in an opening Address, be out of place.

In conclusion I have, I trust, shown how important a part water plays as an agent of metamorphism, not only at and near the surface of the earth, but at plutonic depths. We have seen that the molten granite of the Satlej Valley, which was given as an illustration of a fluid igneous magma, contained a considerable proportion of water held in solution at considerably above red heat, and that the fluidity of the magma was due to its presence. We also saw that the great heat to which the magma was raised increased the potential energy of the contained water when a relief of pressure opened the way for the intrusion of the molten magma into neighbouring rocks. We also saw that this water was rendered by heat a powerful solvent, and that it carried with it into the adjoining rocks the mineral matter of the granite in solution. We also saw that heat increased the porosity of minerals, facilitated the passage of liquids laden with mineral matter through their pores, and increased the potency of chemical action.

SECTION F.

ECONOMIC SCIENCE AND STATISTICS.

OPENING ADDRESS BY EDWIN CANNAN, M.A., LL.D., PRESIDENT OF THE SECTION.

IF it happened every year that the President of this Section undertook to justify his own existence, I am afraid the Section would become weary. But my four distinguished predecessors have all been drawn from the Civil Service, and though each of us may have doubts about particular branches of the Civil Service, we are mostly willing to allow that as a whole it is at least a necessary evil, so that we do not get apologies from the Presidents who, so to speak, represent the practice of political economy. I hope, therefore, that you will beai with me if I offer some reasons for thinking that the teaching and study of the theory of economics is not, as many people seem to suppose, a wholly unnecessary evil, but, on the contrary, a thing of very great practical utility.

I do not mean to argue that a knowledge of economic theory will enable a man to conduct his private business with success. Doubtless many of the particular subjects of study which come under the head of economics are useful in the conduct of business, but I doubt if economic theory itself is. It does not indeed in any way disable a man from successful conduct of business; I have never met a decent economist who was in a position of pecuniary embarrassment, and many good economists have died wealthy. But economic theory does not tell a man the exact moment to leave off the production of one thing and begin that of another; it does not tell him the precise moment when prices have reached the bottom or the top. It is, perhaps, rather likely to make him expect the inevitable to arrive far sooner than it actually does, and to make him underrate, not the foresight, but the want of foresight of the rest of the world.

The practical usefulness of economic theory is not in private business, but in politics, and I for one regret the disappearance of the old-name "political economy," in which that truth was recognised.

One of the commonest complaints of the time is that there is no text-book of economics which commands any really wide approval, and you may therefore, I think, fairly ask me to explain what I mean by the teaching and study of economic theory before I undertake to prove its practical usefulness in the discussion of legislative and administrative measures. I will

therefore endeavour to sketch as shortly as possible the course of instruction which the modern teacher of economic theory, if unhampered by too close adherence to traditional standards, puts before those who come to him for instruction.

The first, or almost the first, thing he will do is to try to open the eyes of his pupils to the wonderful way in which the people of the whole civilised world now cooperate in the production of wealth. He may perhaps read them Adam Smith's famous description of the making of the labourer's coat, a description which required three generations and three great writers to elaborate in the form in which we know it. Or he will ask them to consider the daily feeding of London. There are, he will point out, six millions of people in and about London, so closely packed together that they cannot grow anything for their own consumption, and yet every morning their food arrives with unfailing regularity, so that all but an infinitesimal fraction of them would be extremely surprised if they did not find their breakfast ready to hand. To prepare it they use coal which has been dug from great depths hundreds of miles away in the Midlands or Durham; in consuming it they eat and drink products which have come from Wiltshire, Jamaica, Dakota, India, or China, with no more thought than an infant consuming its mother's milk. It is clear that there is in existence some machinery, some organisation for production which, in spite of occasional failures here and there, does its work on the whole with extraordinary success. It is easy to be pessimistic, especially when the weather is damp, and we are apt to concentrate our attention, and to endeavour to make others concentrate their attention, on this or that defect, and to forget that the system is not made up of defects, but on the whole works very well. Imagine the report of a really outside observer. In all civilised planets, I have no doubt, there must be an institution more or less resembling the British Association. An economist in Mars, let us say, has been favoured with a glimpse of this island through a new mammoth telescope of sufficient power to let him see us walking about, and he is reporting to Section F what he saw. Will he say that he saw a confused scramble for the scanty natural products of the earth? That most people were obviously in a state of starvation? That few had clothes? And that scarcely any were housed? No, truly; he will be much more likely to report that he saw a wonderfully orderly population, going to and from its work with amazing regularity, without a sign of compulsion or unwillingness; that it appeared to be fed and clothed and housed in a way extraordinarily creditable on the whole to some mysterious organisation, the nature of which he could only guess at.

Having endeavoured to make his pupils recognise that we are organised, and that the organisation works, the teacher will go on to show how it works; why things that are wanted are produced in the places where they can be easiest produced and taken to the places where it is most convenient to consume them; why people go to live in large numbers in spots where it is desirable they should work, and leave great areas sparsely inhabited; why more people are brought up to follow an occupation when the desire for its products increases, and fewer when it decreases; why if the harvest is short the consumption is economised so as to spread it over the year; and so on. The answer to all these questions is of course "self-interest" or "the hope of gain." Durham coal, Wiltshire milk, Danish butter, Jamaica sugar, Dakota wheat and China tea go to London because it pays to send them there. People congregate in London or Belfast because it pays them to work there. More do not come because it would not pay them. Young people leave agriculture and go to towns to make agricultural implements or bicycles because it pays. The consumption of grain is economised and spread over the year because it pays to hold the stock. If people with one accord left off doing what paid we should all be dead in two months.

The reasons why it pays to do the right thing—to do nearly what an omniscient and omnipotent benevolent Inca would order to be done—are to be looked for in the laws of value. This used to be regarded as a somewhat arid subject, but the discussions of recent years, especially the contribution made by Jevons and the Austrian school, have fertilised it. Long ago economists pointed out how the much-abused corn-dealer who held out for a higher price saved the people from starvation; and we now, thanks to the theory of final utility, not only know that it is a fact, but also why it is a fact, that value rises with the extent and urgency of demand, so that when a thing is much wanted, much is offered to those who produce it, or are ready to part with it, and consequently its production is stimulated or its consumption economised, as need be.

This will naturally lead to the question of distribution—the question, that is, why much of the produce falls to the share of one individual and little to that of another; why, in a word, some are rich and others poor. The teacher will here explain that the share of each person depends on the amount and value of his contribution to production, whether that contribution be labour or the use of property. He will show how this system of distribution is essential to the existing system of production, where no man is compelled to work or to allow his property to be used by others, and where every man has legal freedom to choose his own occupation and the uses to which he will put his property. He will beware of claiming for it that it is just in the sense in which justice is understood in the nurseries where jam is given when the children are good. There is, he will explain, no claim on behalf of the system that it rewards moral excellence, but only that it rewards economic service. There is no claim that economic service is meritorious. Whether a man can and does perform valuable economic service does not by any means depend entirely on his own volition. His valuable property may have come to him by bequest or inheritance; his incapacity to do any but the least valuable work may be the result of conditions over which he has had no control. The system exists, not because it is just, or to reward merit, but because it is inextricably mixed up with the system of production. It has one great evil—its inequality. Moralists and statesmen have long seen the evils of great inequality of wealth, and now, thanks to modern discoveries in economic theory, the economist is able to explain that it is wasteful, that it makes a given amount of produce less useful, because each successive increment of expenditure yields, as a rule, less enjoyment to the spender. The teacher will go on to show how this organisation of production and distribution is made possible by the order enforced by Government, and how, in various ways, Government supplements or modifies it; but I shall not enlarge upon this part of the teaching of economics, as its practical usefulness is obvious. My theme is the usefulness of the other part, the explanation of the organisation of production and distribution in so far as it depends on separate property, free labour, and the consequent action of self-interest.

In the first place, I maintain that the widespread dissemination of such teaching would help to do away with a vast amount of most disastrous obstruction of necessary and desirable changes. Take, for example, the obstruction offered to changes in international trade. Of course every conceivable argument has been used by different writers in wholly different circumstances for obstructing the cooperation of mankind in production, as soon as it oversteps a national boundary. But what is the real support of this kind of obstruction? Obviously the fact that certain producers, or owners of certain means of production, are damaged by an increase in the importation of a particular article. Their loss, their suffering, if their loss is severe enough to deserve that name, appeals to popular compassion, and their request for "protection" is easily granted, the new trade is nipped in the bud, and things are forced to remain in their accustomed channels. The same principle is not applied as between county and county or between province and province, simply because there is then visible to everyone an opposing interest, the interest of the new producers, within the hallowed pale of the national boundary. Adam Smith tells us that when the great roads into London were improved, some of the landlords in the home counties protested on the ground that the competition of the more distant counties would reduce their rent. The home counties did not get the protection they wanted, because it was obviously to the interest of the more distant counties that they should not have it. These two interests being balanced, the interest of the consumer, London, turned the scale. So it usually happens that beneficial changes in internal trade are allowed to take their course without obstruction because the votes of two sets of producers counteract each other, and the consumer's interest settles the question. But in international trade one of the two sets of producers is outside the country; it consists of hated foreigners, the fact that it will benefit is an argument against rather than for the threatened change in trade, and the consumers therefore feel it patriotic to sacrifice their own interest and vote for protection. But if they were properly instructed in economic theory they would see at once that such magnanimity is entirely misplaced. They would see that it would cut away all international trade, since, if

there were no fallacy involved in it, the stoppage of each import taken separately would benefit home producers and damage foreign producers. Even if some of the imported commodities could not be produced at all at home, substitutes, more or less efficient, could be produced and give all the more employment. Having acquired some notion of the advantages of cooperation and the territorial division of labour, the consumers would regard this as a *reductio ad absurdum*, and after thinking a little further they would soon see that, after all, there is another set of producers, actual or potential, within the country who will gain—namely, the producers, present or future, who will supply the articles which are to go abroad in exchange for the new import. They will see that what they are asked to do is not to maintain the amount of national production, but merely to prevent a change in its character which will be accompanied by an increase in its amount.

Take another example of Chinese obstructiveness to desirable change. As great cities grow, it becomes convenient that their centres should be devoted to offices, warehouses and shops, and that people who work in these places, and still more their families, should live in the outskirts. I do not know that anyone has denied this. Certainly the great majority are willing to admit it. At one time it is believed that a quarter of a million people lived in the square mile comprised within the City of London; no one supposes that would be convenient now. There is no reason to suppose that further change in the same direction will not be desirable in the future. Yet, incredible as it will appear to future generations, public opinion, the House of Commons, the London County Council and some town councils think, or at any rate act as if they thought, that the process has now gone far enough and ought to be stopped; as if the state of things reached about the year 1891 was to be permanent, to last for ever and ever. Private owners are indeed still allowed to pull down dwelling-houses and erect shops and offices, but they are abused for doing so, and their liberty is at least threatened. But if a new railway or a new street is made —in all probability with the intention of increasing the accessibility of the centre from the suburbs—if even a new London Board School is built, and houses inhabited by persons who have less than a certain income are pulled down in any of these processes, it is required by law or parliamentary resolution that other houses for these people must be built in the neighbourhood. So it comes about that there are in quarters of London most unsuitable for the purpose enormous and repulsive barrack dwellings, the sites of which are devoted *in secula seculorum* to the housing of the working classes; while the immense cost of devoting them to this instead of to their proper purpose is debited to the cost of improving the facilities for locomotion or to education, and is defrayed principally by the rates on London property, which chiefly consists of houses, and to some extent by the higher charges on the railways consequent on the restriction of facilities for extension. Fifty pounds a head is the average loss involved to the rates of London on every man, woman and child for whom these dwellings are provided. Such is the wisdom of practical men uninformed by instruction in economic theory.

This palpable absurdity could never have been perpetrated if the general working of the economic organisation had been understood. In that case it would have been seen at once that the extrusion of over 200,000 inhabitants from the City of London in the past, which is admitted to have been desirable, was effected by the quiet operation of the laws of value. It would have been seen that as it became desirable to turn the City to other purposes, the ground in the City became too valuable to use as bedrooms and as living-rooms for mothers and children, and this increase of value drove out the 200,000 inhabitants. It would have been seen that the change had not come to an end, and no responsible body would have dreamt of putting themselves in opposition to it by buying sites and writing them down to 2 per cent. of their actual value in order that they might be tied up for ever and ever to be the homes of a certain number of persons with less than a certain income. If some unusually dense individual who had failed after many attempts to pass his examination in economic theory had proposed the policy which has been adopted, he would have been asked two questions: first, "What peculiar sanctity is there about the position occupied in the closing years of the nineteenth century? Why should this be stereotyped for all time? Why should not the position at the end of the seventeenth century have been maintained? Why should we not endeavour to restore the working classes to their old home in the City, and remove the Bank of England to Tooting?" Secondly, "Whom do you imagine you will benefit by the policy you propose?"

It is difficult to conceive of any answer to the first question. To the second the reply of the dunce would of course be that he thought the policy proposed would benefit the people housed on these expensive sites. This answer would at once be condemned as unsatisfactory. To build houses on land worth 100,000*l.*, and let them to the first-comers of respectable antecedents at rents which would pay if the land were worth 2000*l.*, would be a very stupid sort of almsgiving if these respectable first-comers actually got the difference between the interest on the 100,000*l.* and the 2000*l.* But no one supposes that they do get this difference or any considerable part of it. The difference is almost entirely pure loss to the community. The chief immediate effects of the policy are, first, to retain in the centre the men, women and children who inhabit the dwellings; secondly, to retain other workers who perform various offices for these inhabitants; and thirdly, to ensure a supply of labour for factories which would otherwise (to the advantage of everyone concerned) be driven into the country by the pressure of the high wages necessary to bring workmen to the centre or to pay their house rent if they lived there.

So much for the utility of economic theory in preventing obstruction of desirable changes. My second claim on its behalf is that it serves to hinder the adoption of specious but illusory projects. This, I think, may be illustrated by examples closely connected with those which we have already considered under the head of obstruction.

The people who are most anxious to obstruct changes in the channels of trade which are coming about of themselves because they are profitable, are often extremely anxious to promote changes which will not come about of themselves because they are not profitable. For this end one of their most favourite devices at present is a State or municipal subsidy to locomotion or transport between particular points. So we have shipping subsidies, free grants to light railways, the construction of unprofitable telegraph lines by the Post Office, and the advocacy, at any rate, of the construction of unprofitable tramways by municipalities. The practical man, uninstructed in economic theory, feels uneasy about such projects because he does not see where he is to stop, and he feels obscurely that a universal subsidisation would mean ruin. But he does not see why he should not go a little way, and he goes sufficiently far to involve a loss quite worth considering. A knowledge of economic theory would come to his assistance by showing him that, as a rule, the most profitable enterprises are those which it is most desirable to undertake first, and that the subsidisation of the less profitable does not create new enterprises, but merely changes the order from the more desirable to the less desirable. I suppose that if in 1830 Parliament had offered a sufficient subsidy a railway might have been at once made and worked from Fort William to Fort Augustus, to the great satisfaction of the inhabitants of Fort Augustus and the intermediate places. But it is obvious that it was more desirable, in the interests of the whole community, that the railway from Fort William to Fort Augustus should wait for seventy years, and that the railway from Manchester to Liverpool, and many others, should be made first.

Then, too, we find people who are not quite so stupid as to think the working classes should always remain in the places where they were at the end of the nineteenth century, alleging that the way to cure overcrowding is for local authorities to enter the building trade in a general way, and build houses inside or outside their districts, wherever it seems most convenient. To the mind uninstructed in economic theory it seems obvious that the larger amount of housing there is the less overcrowding there will be, and that the more housing local authorities provide the more housing there will be. Economic theory, with its explanation of the general working of the organisation of production, suggests two objections. First, an addition to the housing in any locality will not be effectual in diminishing overcrowding, in so far as it attracts new inhabitants to the spot; a policy which assumes that the comparative plentifulness of houses is not a factor in the determination of the enormous and perpetual migration of people from place to place which is indicated in the tables of birthplaces and births and deaths in the census, is doomed to failure. Secondly, economic theory suggests the reflection that the mere fact of a local authority building some houses will not cause the whole number to be greater, if for

every house built by the local authority one less is built by private enterprise, and that this is very likely to happen. Houses have been built by private enterprise in the past, and in these houses nearly the whole population is at present housed. I have seen an enthusiast for municipal housing stand in the empty streets of a town late at night, when every soul in the town was evidently housed, and say, in a tone of conviction, "Private enterprise has failed." In that town four small houses had been built by municipal enterprise and more than ten thousand by private enterprise, and private enterprise was adding hundreds every year, while the housing committee of the corporation was meeting once a year to re-elect its chairman. Is it likely that private enterprise will build as much when it is competed with or supplemented by—the term does not matter—municipal enterprise? Why should it? If the municipality turned baker, would the private bakers continue to bake as much bread? Is not the attempt to stop overcrowding by inducing local authorities to build houses exactly the same thing and just as absurd as it would be to attempt to cure under-feeding by opening municipal butchers' and bakers' shops?

In the long run, I admit, experience teaches. Protection has fallen once in this country, and I have little doubt that it will fall again if it becomes considerable. The policy of obstructing the removal of dwellings from the centre of a great city already excites opposition in the London County Council, though unanimity still reigns in those last homes of extinct superstitions, the Houses of Parliament. Chancellors of the Exchequer and finance committees may be trusted to offer a stout resistance, on what they call financial grounds, to any really great development of the system of subsidies. There is hope even that the municipal building policy may be checked by the laborious inquiries which show by statistics what everyone knows, that the poor are ill-fed and ill-clothed as well as ill-housed, and therefore lead people to consider how the poor may be made more able to pay for houses, among other things, instead of simply how houses may be built in the absence of an effective demand for them. But I claim that, in matters such as these, a more widespread appreciation of economic theory, and the quickened intelligence which that would produce, would save us much painful experience, many expensive experiments, and an enormous mass of tedious investigation.

Thirdly and, at any rate on the present occasion, lastly, I claim that the teaching and study of economic theory has great practical utility in promoting peace and good will between classes and nations.

Between classes within the same nation the peacemaking influence of economic theory lies chiefly in the fact that it tends to get rid of that stupid cry for "rights" and "justice" which causes and exacerbates industrial and commercial quarrels. When demand for some commodity falls, or supply from some new quarter arises, and profits and wages fall, the workers cry out that they are being unjustly treated, because they have the unfounded belief that reward is or ought to be proportional to moral merit, and they are not conscious of any diminution of their moral merit. They demand a living wage or a minimum wage and employment for all who happen to have been hitherto employed in the trade, rend the air with complaints, and get subscriptions from a compassionate but ill-informed public. We cannot, of course, expect people who suffer by them to regard even the most beneficial operations of the economic organisation with enthusiasm or even satisfaction. It would be absurd to do so. But all the same, it is true that a wider apprehension of the fact that it is only by raising and lowering the advantages offered by different employments that production is at present regulated so as to meet demand would not only diminish the dissatisfaction, but also, which is more important, diminish the actual suffering by causing transitions to be less obstinately resisted. The present fashion of deploring rapid changes of trade and dwelling-place is a most unfortunate one; the ordinary forms of labour do not, as a matter of fact, require such specialised ability that there should be much difficulty in changing from one to another; and surely it is much better for a man to work at several different things at different places in the course of his life than to stick for ever in the same place, surrounded by the same objects, going through the same monotonous round of duties. Anything which will weaken the present obstructive sentiment and lead people to regard the necessity of a change of employment or residence as a temporary inconvenience rather than a cruel injustice is to be warmly welcomed.

It is not, however, only the poor and the industrious who would be taught by a greater knowledge of economic theory not to kick against very necessary pricks. The rich, both industrious and idle, would be taught to be far more tolerant than they are of attempts to diminish inequality of wealth by reducing the wealth of the rich as well as increasing that of the poor. The economist may be a little annoyed with the workman who insists that he ought to have thirty shillings a week for producing something worth fifteen shillings, or five shillings, or nothing at all, but he can only have hearty contempt for the millionaire who holds up his hands in holy horror and murmurs "confiscation," "robbery," "eighth commandment," when it is proposed to relieve him of a fraction of a farthing in the pound in order to bring up destitute orphans to an occupation in which they may earn twenty-five shillings a week. The sanguine teacher of economic theory has hopes of making even such a man see that he has his wealth, not because Moses brought it down from Sinai, or because of his own super-eminent virtue, but simply because it happens to be convenient, at any rate for the present, for society to allow him to hold it, whether he obtained it by inheritance or otherwise. In other words, that private property exists for the sake of production, not for the sake of the particular kind of distribution which it causes. Some, I know, say that the rich are so few that it does not much matter whether they acquiesce in the measure meted to them or not; but that is not the teaching of history, and I think you will agree with me that for the progress of the whole community it is, in practice, quite as important to secure the acquiescence of the rich as of the poor.

In regard to international relations, the first business of the teacher of economic theory is to tear to pieces and trample upon the misleading military metaphors which have been applied by sciolists to the peaceful exchange of commodities. We hear much, for example, in these days of "England's commercial supremacy," and of other nations "challenging" it, and how it is our duty to "repel the attack," and so on. The economist asks what is "commercial supremacy"? and there is no answer. No one knows what it means, least of all those who talk most about it. Is it selling goods dear? Is it selling them cheap? Is it selling a large quantity of goods in proportion to the area or of the country? or in proportion to its population? or absolutely, without any reference to its area or population? It seems to be a wonderful muddle of all these various and often contradictory ideas rolled into one. Yet what a pile of international jealousy and ill-feeling rests on that and equally meaningless phrases! The teacher of economic theory analyses or attempts to analyse these phrases, and they disappear, and with them go the jealousies suggested by them.

When misleading metaphors and fallacies are dismissed, we are left with the facts that foreign trade—the trade of an area under one Government with areas under other Governments—is merely an incident of the division of labour, and that its magnitude and increase are no measures of the wealth and prosperity of the country, but merely of the extent to which the country finds it convenient to exchange commodities of its own growth or manufacture for commodities produced elsewhere. If the city of York were made independent, and registered its imports and exports, they would come out far larger per head of population than those of the United Kingdom or any other great country. Should we be justified in concluding York to be far richer than any great country? If means were discovered of doubling the present produce of arable land with no increase of labour, much less corn would be imported into Great Britain and less of other goods would be exported to pay for it; the foreign trade of the country would consequently be diminished, but would the people be any less prosperous? What jealousies, heart-burnings, and unfounded terrors leading to hatred would be extinguished if only these elementary facts were generally understood!

To anyone who has once grasped the main drift of economic theory, it will be plain that the economic ideal is not for the nation any more than for the family that it should buy and sell the largest possible quantity of goods. The true statesman desires for his countrymen, just as the sensible parent desires for his children, that they should do the best paid work of the world. This ideal is not to be obtained by wars of tariffs, still less by that much greater abomination, real war, with all its degrading accompaniments, but by health, strength and skill, honesty, energy and intelligence.

NOTES.

A NOTE in the *Times* states that the continuance of the meteorological work at Ben Nevis Observatory is practically assured. The staff had received notice that their services would not be required longer than October, but so satisfactory have been the offers of support that this order has been cancelled and winter stores have already been conveyed to the summit. The composition of the departmental committee of inquiry promised by Mr. Balfour will be announced shortly. So great has been the clamour against the threatened stoppage of the valuable work at the Observatory that it is confidently believed that the Treasury, guided by the advice of the committee, will enable the governing body to place the institution on a satisfactory financial footing of a permanent kind.

THE thirteenth annual general meeting of the Mining Institute of Great Britain was opened on Tuesday last at Newcastle-upon-Tyne, and at the same time the jubilee meeting of the North of England Institution of Mining and Mechanical Engineers, upon the foundation of which the Mining Institute was laid, was held.

THE *Pioneer Mail*, Allahabad, states that a donation of 50,000 rupees has been made by the Government of India to the Pasteur Institute of India at Kasauli, and the Punjab Government has handed over to the central committee of the Institute as a free gift Drumbar House at Kasauli for the accommodation of the poorer class of European and Eurasian patients, while Sir Charles Rivas has given 10,000 rupees to the Institute for the years 1902–3; grants have also been made by the Governments of Burma and the United Provinces of Agra and Oudh, and the chief commissioners of the Central Provinces and Assam. It is pointed out by our contemporary that no grants have been made by the Governments of Bombay and Madras.

THE next international conference on tuberculosis will be held in Berlin from October 22 to 26, and a provisional programme of the proceedings has just been issued. The subjects suggested for debate are the position of Governments with regard to the prevention of consumption; obligation to give information to the police; organisation of dispensaries; the task of schools with regard to the prevention of consumption; precautions against the dangers of milk; tuberculosis during infancy; protection of labour and prevention of consumption; classification and different modes of accommodating consumptives. In addition to the consideration of the foregoing questions, the members of the congress will inspect various establishments for the treatment of tuberculosis, and preparations are being made for a number of social functions.

THE sixth International Congress of Hydrology, Climatology and Geology will be opened at Grenoble on Monday, September 29, and continue in session until the following Saturday.

THE ninth expedition of the Liverpool School of Tropical Medicine has just proceeded to the Suez Canal to institute preventive measures against malaria. Major Ronald Ross, F.R.S., the leader of the expedition, will be joined at Brindisi by Sir William MacGregor, the Governor of Lagos, who has expressed a desire to witness the operations at Ismailia. The work will be begun immediately on the arrival of the expedition, and extensive operations commenced against mosquitoes.

AN archæological expedition, composed of seven Japanese, has just started for Central Asia, under the leadership of Count Otani Kozui and M. Watanabe Tetsushin. The object of the expedition is to search for the Buddhistic remains in Central Asia, India and China, and to trace so far as is possible the course of Buddhism from its source northwards and eastwards to Japan.

WE have to report the death of Dr. H. von Wild at Zürich on September 5, in his sixty-ninth year. He was director of the Central Meteorological Station at Berne from 1863–5, director of the Russian Meteorological Service from 1868–1895, and president of the International Meteorological Committee from 1882 1892. He was the author of numerous works on meteorology and terrestrial magnetism, and the inventor of a wind-vane with a simple swinging wind-force plate which was much used in Switzerland. Prof. von Wild was probably best known to our readers as the editor of the Russian *Repertorium der Meteorologie*, which contained valuable elaborate discussions of scientific subjects. His greatest work was "Temperatur-Verhältnisse des russischen Reiches," which embraced 349 pages of text and 271 plates.

THE death is announced of Prof. J. J. Hummel, principal of the dyeing department of the Yorkshire College, Leeds; also of Mr. Alexander Sutherland, registrar of the University of Melbourne, and author of, among other works, "The Origin and Growth of the Moral Instinct."

LETTERS received from Uganda give a good account of the progress of Mr. Budgett, Balfour travelling student of Cambridge, on his zoological mission to the Semliki. On July 13, he writes that he was proposing to start next day from Kampala for Lake Albert, where he would probably stay at Batyaba, near the Nile end, the Polypterus which he was in quest of being stated to be abundant at this spot. Afterwards his plans were to proceed southward to Fort Portal and thence to the Semliki valley, where he would make a general collection and look after the okapi in the neighbouring forest. Mr. Jackson has most kindly allowed Mr. Budgett to have the assistance of one of his trained taxidermists.

A COMMISSION will shortly leave England to settle the boundary line between the western portion of northern Rhodesia and the Portuguese territory. The commissioners selected for the purpose are Lieut.-Colonel Jackson and Lieut.-Colonel J. M. Woodward, of the Intelligence Department of the War Office, and Colonel Harding, the resident of the British South Africa Company in Barotse-land, will probably accompany the party. As the country to be traversed is very little known, it is much to be desired that a naturalist should be attached to this expedition, and we are informed that the authorities of the Natural History Museum have been consulted on the subject. The commissioners, it is said, are quite favourable to this being done, if the necessary arrangements can be made.

A DESPATCH has been received at New York from Lieutenant Peary, dated from Chateau Bay, Labrador, stating that he is homeward bound on board the *Windward* and that all is well.

AN international marine laboratory is, it is stated, to be established at Christiania under the direction of Dr. Fridtjof Nansen.

Science announces that Mr. William H. Wright, of the Lick Observatory, has been selected to take charge of the D. O. Mills expedition, which is at present being got ready for a two years' stay in Chile to make a special study of the stars of the southern hemisphere. The superintendence of the erection of the observing station and the inauguration of the work of the expedition will be undertaken by Director W. W. Campbell.

A FUNGUS foray in connection with the Yorkshire Naturalists' Union will take place in Arnecliffe Woods and other portions of Eskdale from Saturday, September 27, to Thursday, October 2.

DURING the past week, Vesuvius has been showing a certain amount of activity and Stromboli has also been active, frequent explosions and detonations having taken place and much

black smoke having been emitted. Travellers from Alaska report that great volumes of steam are rising from the volcanoes Redoubt and Iliamna in the Augustine Mountains, while the Redoubt is also throwing up immense clouds of smoke. According to advices from Honolulu dated September 3, Mount Kaluaha is active and is ejecting streams of fire. M. Lacroix, of the French Natural History Museum, left on Tuesday last to begin his work at Martinique.

ACCORDING to a Reuter telegram from Rome, the Italian postal authorities have examined a scheme submitted by an engineer, named Piscicelli, for the establishment of an electric postal service. It is proposed, by means of this system, to transmit letters in aluminium boxes, travelling along overhead wires at the rate of 400 kilometres an hour. A letter could thus be sent from Rome to Naples in twenty-five minutes and from Rome to Paris in five hours. A technical commission has been appointed to report on the system befoie instituting a series of experiments between Rome and Naples.

IT is stated in the *British Medical Journal* that a somewhat new departure is about to be made by the North-Western Railway (U.S.), the headquarters of which are in Chicago. The plan is to equip every freight and passenger train with emergency chests containing splints, cotton bandages, antiseptics, restoratives, &c., and to open a school of instruction in first aid to the injured. The employés on all trains are to be required to attend the same and demonstrate that they comprehend the purpose of the teaching. The great purpose of the plan is to save lives, in the case of injuries, by the prompt and intelligent use of modern principles of treatment such as could be reasonably applied by an ordinary train crew, the contention being that an injured person in such circumstances will be able to reach the nearest hospital in a far better condition, and that his chances in all respects will be correspondingly heightened.

THE *Electrician* states that a patent has just been issued in America for a coin-controlled X-ray machine for public use. The external appearance of the apparatus is similar to that of the automatic kinematograph machines so commonly seen on railway platforms and other places. The observer places a coin in the slot, moves a lever, puts his hand, or whatever he wishes to examine, into a box without any sides, and looks down at it through a fluorescent screen which forms the top of the box. The coin, on being inserted, closes the primary circuit of an induction coil worked by a few dry cells, and the vacuum tube is in a position immediately below the object to be observed.

SOME four years ago, the Belgian Government offered a prize of 50,000 francs for a paste for matches which should not contain white sulphur. The commission appointed to judge the results of the competition has now reported that after careful experiment and analysis it finds that none of the products so far submitted fulfil the required conditions, being defective in inflammability, ignite on any surface, or in igniting eject inflammable matter containing some poisonous substance.

THE sum of 5000 dollars has, according to *Science*, been bequeathed to the Astronomical Society of the Pacific by Mr. John Dolbeer, of San Francisco. The money will be invested, and the interest devoted to the diffusion of astronomical knowledge.

A GOTHENBURG physician has, it is stated in the *Journal* of the Society of Arts, invented an apparatus by which milk can be brought into the foim of powder similar in appearance to flour, and possessing all the qualities of milk in concentrated form, moisture excepted. It is maintained that the flour is perfectly soluble in water, and can be used for all purposes for which ordinary milk is employed. It is also claimed for it that it does not get sour, or ferment, and in its dry state is not sensitive to changes in the weather. The cost of its production is estimated at 1*s.* 1*d.* per 106 quarts.

THE zoological station of Arcachon, under the direction of M. le Dr. F. Jolyet, professor of medicine in the University of Bordeaux, is now in full work, but we are sorry to learn that the laboratories are not fully occupied. Arcachon, with its grand "basin" always accessible, and large fishing fleet, is such a favourable spot for the marine zoologist that we are surprised that such should be the case. The report of the station for 1900–1 contains the results of several pieces of scientific work of much interest. Arcachon is a good place for the student of animal electricity, Torpedo being of common occurrence there. A new subsidiary station has recently been opened at Guethary, a small bathing-place near St. Jean de Luz, which is stated to have an excellent beach for dredging operations.

THERE are now three examples of the Grevy's zebra (*Equus grevyi*) in the Regent's Park Gardens, placed under the Zoological Society's care by the order of the King. Two of these were presented to His Majesty by the Emperor Menelik, and the third is the survivor of a pair presented by the same Emperor to Queen Victoria. Unfortunately, they are all three of the female sex. But Colonel Harrington, the British representative in Abyssinia, has most kindly presented to the Zoological Society a pair of this zebra now living in his compound at Abis Abeba, and it has been arranged to send out one of the keepers to bring them home next month, so that there is a good chance of this magnificent animal, by far the largest and finest of all the wild Equidæ now in existence on the earth's surface, being permanently established in England.

THE weekly weather reports issued by the Meteorological Council up to August 30 show that in the principal wheat-producing districts, which include the eastern portions of Great Britain and the south of England, the only part where the rainfall had reached the average amount was the east of England; in the east of Scotland the deficit was 3 inches. In the principal grazing districts, which include the western portions of Great Britain, the south-west of England and the whole of Ireland, the only part where the rainfall had reached the normal amount was the north of Ireland; in the south-west of England the deficit was 5 inches. These figures will be somewhat modified by the heavy fall that accompanied the severe storm which passed along St. George's Channel and the Irish Sea on the night of September 2–3, when the amount exceeded an inch both in the north and south of Ireland; and in the counties of Wicklow and Dublin, which lay in the direct path of the centre of the storm, the fall in twenty-four hours amounted to nearly 3 inches. Nearly 2 inches fell on parts of the south coast of England during the same night.

METEOROLOGISTS are much indebted to Mr. R. C. Mossman for the publication of part iii. of his valuable papers on the meteorology of Edinburgh, which appears in a recent number of the *Transactions* of the Royal Society of Edinburgh. The present paper deals more particularly with new monthly and annual averages for the ten years 1891–1900 and the fifty years 1851–1900, and includes, *inter alia*, means of temperature and pressure, and rainfall values for periods varying from 124 to 137 years. An appendix continues the very interesting account, commenced in part ii., of remarkable atmospheric and celestial phenomena that have occurred in past years, and contains references to two events as far back as the twelfth century. The complete work undoubtedly forms the most useful and comprehensive discussion of the climatology of Edinburgh that exists.

A PAPER by Mr. Walter Wesché in the *Journal* of the Royal Microscopical Society for August bids fair to throw light on the

relations between the mouth-organs of diptera and those of other insects. Even in such dipterous genera as Tabanus and Culex, the full number of mouth parts of a typical insect is not present, the absent parts being one pair of palpi, which are commonly regarded as the labial palpi. In other families, such as the Muscidæ and Syrphidæ, where mandibles and even maxillæ are absent, chitinous structures are visible on the dorsal side of the labium representing the aborted parts. Mr. Wesché now finds that certain members of the Muscidæ are provided with a second pair of palpi in addition to those always present and which are generally regarded as maxillary. "In several species of the Anthomyia family, in the genera Hyetodesia, Spilogaster and Hydrotea, are to be found at the base of the labium and hypopharynx, and connected with the apodemes or levers that work those parts, two hairy processes, one on each apodeme. These are jointless, chitinous in structure, and have much the appearance of ordinary palpi." In *Hyetodesia basalis*, the organs measure about 0·003 inch (0·085 mm.) in length, while in *Spilogaster duplicata* they are the same length and about half the breadth. In other species of the same family, the rudiments are reduced to a few hairs and a minute tubercle; in the Sarcophagidæ, rudiments are found in *Myiocera carinifrons*; in the Muscidæ proper in *Musca corvina* and *M. domestica*, and the palpi have also been found in the families Sepsidæ, Opomyzidæ and Borboridæ. The discovery of these rudimentary palpi, which are undoubtedly maxillary, leads to the conclusion that the palpi so conspicuous on the proboscis of many flies are not the maxillary but the labial palpi.

EIGHT years ago Prof. Omori studied the distribution in time of the after-shocks of several great Japanese earthquakes, and concluded that a strong earthquake is almost invariably followed by weaker ones, and a destructive one by hundreds or even thousands of minor shocks, which gradually diminish in frequency and strength, but may continue to be felt for several years. In a recent valuable memoir (*Boll. Soc. Sism. Ital.*, vol. viii. pp. 17–48), Dr. Cancani has investigated the distribution in intensity of the after-shocks of three hundred Italian earthquakes, all strong enough to produce at least slight damage in buildings. Such earthquakes, he finds, are never isolated, but are always preceded or followed by others generally weaker. The total duration of an earthquake-period (perhaps earthquake-series or group would be a better term) is a function of several variables, but depends especially on the depth of the seismic focus. When the depth is small, the earthquake-period is of brief duration, generally about ten days; when moderate, the after-shocks may continue for about three months, and when the depth is great they may last for several years. In 70 per cent. of the earthquake-periods, the strongest shock occurred during the initial phase or first tenth part of its total duration.

THE Report of the Botanical Exchange Club of the British Isles for 1901 has been delayed, as the distributor, the Rev. E. S. Marshall, explains, in order to obtain critical opinions on some of the specimens. The number of specimens sent in by twenty-five contributors amounts to more than 2700. Many of these are varieties or hybrids, others represent new localities. Several new species are recorded for Lancashire, notably *Helleborus viridis* and *Helleborus foetidus*, *Scirpus caricis* and *Carex teretriuscula*. A discovery of *Euphorbia exigua* in limestone crevices on the north coast of Wales lends support to the view that it is a native of Britain. *Statice Limonium × rariflora* and *Salicornia lignosa*, both growing near Bosham in west Sussex, have elicited interesting criticisms, but the most important collection, *Diotis candidissima*, was made by Mr. C. P. Hurst in Wexford. There it grows in quantity on a sandy bar, as may be seen from the two illustrations given, which are reproduced from photographs taken by the finder.

A NUMBER of papers dealing with electric traction, which were read before the Association Française pour l'Avancement des Sciences last month, are summarised in *L'Éclairage electrique* for August 23. These will be found especially useful by those who are interested in accumulator traction, whether for tramways or automobiles, as the suitability of the accumulator is considered from several points of view. The general conclusions are not very favourable to the accumulator in its present commercial form, although accumulator traction was voted a perfectly practical solution of the problem of running a tramway electrically in a position in which trolley wires were inadmissible. Accumulators were not, however, regarded as so suitable for automobiles, as their weight involved difficulties in the construction of the cars and tyres which were not so important in a tramcar heavy in itself and running on a prepared track. For a public service of electric automobiles, the only system considered practical was one in which power was obtained from a trolley wire, with omnibuses or carriages running on the ordinary roadway, a system which obviously possesses some advantages over even the electric tramway.

A BRIEF account of the latest apparatus for rendering air respirable in a closed space is described by M. Desgrez in the *Bulletin* of the French Physical Society, No. 185, the apparatus having been devised by M. Desgrez in collaboration with M. Balthazard. The underlying principle is the decomposition by water of sodium peroxide, with liberation of oxygen, absorption of carbon dioxide and destruction of the toxic products of respiration. The apparatus consists of (1) a distributor which, by the action of clockwork, drops the peroxide into water at regular intervals; (2) a cubical steel box containing the water; and (3) a ventilating fan. A refrigerator is also supplied, as a general rule, to counteract the heating effects of the chemical reactions. A complete apparatus has been constructed, capable of enabling a man to work for at least three-quarters of an hour in a closed space, and weighing in all about 12 kilograms.

THE current number of the *Proceedings* of the Edinburgh Mathematical Society contains a note on decimal coinage and approximations by Mr. J. W. Butters. Apart from the advantages of a decimal system of coinage, the author calls attention to several points which cannot be too strongly emphasised. One is the common complaint as to the time wasted by learners in using long and cumbersome methods (often calculating sums of money to a fraction of a penny with a long numerator and denominator), from ignorance of the use of decimals. This evil, the author thinks, could be remedied by teaching decimals before vulgar fractions, as is often done in Germany. Another point is the use of the unit's figure instead of the decimal point as a landmark in counting places in multiplication and division. Everyone knows, or should know, that the characteristic of a logarithm is given by the number of places that its first significant figure is to the left of the unit's figure, whereas if the decimal point is taken as the landmark, we are told that the characteristic is one more or one less than something or other and confusion may arise. Mr. Butters suggests that the decimal point be called the unit's point and regarded as used for fixing the unit's place, and he shows how multiplication and division of decimals are simplified by adopting this view. The necessity for such a change is emphasised by the fact that the ordinary method of dividing decimals fails to give the correct *remainder*. Finally, the author points out the saving in labour in using decimals of a pound and contracted methods for ordinary calculations.

THE current number of the *Journal* of the Anthropological Institute fully maintains the great reputation which that publication has earned. There are three papers on customs and beliefs of various African tribes, one on a remarkable musical

instrument of the Bushmen and two papers on Kabyle pottery. Indian ethnography is represented by one paper and Malay ethnography by three; other papers deal with the Nicobars, Sarawak, Tasmania, Tonga and New Zealand. The range is wide alike in geography and matter, so that practically all departments of anthropology are represented, and the twenty plates are of exceptional interest and excellence.

ANTHROPOLOGY is to be congratulated in having found so able and enthusiastic a student as the Rev. J. Roscoe, of Uganda, whose paper on the manners and customs of the Baganda is of extreme interest. Amongst other important novelties, it contains an account of a typical form of totemism which was previously unrecorded among the Baganda, and even the magical aspect appears to be present. Very suggestive are the customs relating to twins and the sympathy between human beings and plantains. The people appear to have but recently emerged from matriarchy into patriarchy.

ANOTHER important paper in the same *Journal* of the Anthropological Institute is that on some animistic beliefs among the Yaos of British Central Africa, by the Rev. A. Hetherwick. The Yao present us with three stages of animistic belief, (1) the *lisoka* or human shade, the agent in dreams, delirium, &c.; (2) this *lisoka* regarded as *mulungu* and an object of worship, the controller of the affairs of this life; and (3) *mulungu* as expressing the great spirit agency, the creator of the world and of all life. Between these three conceptions of the spirit nature no definite line can be drawn.

In the concluding portion of his article on "Regeneration in Plants" in the *Biologisches Centralblatt*, Prof. Goebel has an instructive chapter on the disposition of adventitious developments which follow upon injury or wounding. That it may be referred to a polarity depending upon internal, not external, factors follows from Vochting's researches. Tracing the argument back further—*e.g.*, what does polarity mean?—Beijerinck's hypothesis of an upward current shoot forming and a downward current root forming is accepted in part, and experiments which can be explained upon this hypothesis are mentioned. Sometimes, however, this is not satisfactory, and Prof. Goebel finds that a more general and correct explanation of certain anomalous cases is obtained by a consideration of the direction of flow of the food current. Finally, Prof. Goebel regards with favour the idea of a controlling enzyme as postulated by Beijerinck.

The Geological Survey of Western Australia, in *Bulletin* No. 6 (1902), gives the results of the chemical and mineralogical research work carried out by Mr. E. S. Simpson since the laboratory was established in 1897. There are notes on native gold and its compounds with tellurium and other elements, as well as notes on various ores, on coal, peat, clays, water, and on sundry intrusive rocks.

WE have received three important papers devoted to embryology and development. Two of these, dealing respectively with amphibians and the brachiopod Lingula, appear in a recent issue of the *Journal* of the Tokio College of Science. The third, by Dr. J. A. Masterman, which is published in the *Transactions* of the Royal Society of Edinburgh, treats of echinoderm development.

THE August issue of the *Journal* of the Department of Agriculture of Victoria is composed of the annual reports of the officers in charge of the various branches of the Department, prefaced by a brief summary of the whole by Mr. S. Williamson Wallace, the Director of Agriculture for the colony. The reports are interesting reading, and tell of much good work done on scientific lines at a comparatively small cost.

THE *Scientific American*, New York, for August 30, contains an illustrated article, by Mr. F. Moore, upon the United States Naval Observatory.

PART 4 of the new and cheaper edition of Kerner and Oliver's "The Natural History of Plants" has reached us from Messrs. Blackie and Son, Ltd.

MR. BERNARD QUARITCH has just issued a new part, devoted to India and the Far East, of his "Catalogue of Works on Oriental History, Languages and Literature," containing particulars of many rare and valuable books.

THE additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus sinicus*) from India, presented by Mr. J. H. Osborne; two Diana Monkeys (*Cercopithecus diana*) from West Africa, presented by Mr. E. Skinner; a Levaillant's Cynictis (*Cynictis penicillata*) from South Africa, presented by Mr. E. C. S. Jervis; two Cape Eared Owls (*Asio capensis*) from Africa, presented by Captain Fraser; a Diana Monkey (*Cercopithecus diana*), a White-thighed Colobus (*Colobus vellerosus*), two Grey-headed Sparrows (*Passer simplex*) from West Africa, a Simpae Monkey (*Semnopithecus melalophus*) from Sumatra, a Salle's Amazon (*Chrysotis ventralis*) from St. Domingo, two Striated Tanagers (*Tanagra striata*) from Buenos Ayres, a Blue Sugar-bird (*Dacnis cayana*), an All-green Tanager (*Chlorophonia viridis*) from Brazil, deposited; two Swinhoe's Pheasants (*Euplocamus swinhoii*), an Argus Pheasant (*Argus giganteus*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

ANOTHER NEW COMET.—From information received, through Mr. E. W. Maunder, from Mr. John Grigg (a member of the Cometary Section of the British Astronomical Association), of Thames, New Zealand, it appears that the comet discovered by Perrine, which, if this news is confirmed, has been erroneously named 1902 *b*, is not the second, but the third comet discovered this year.

Mr. Grigg says that whilst using his $3\frac{1}{2}$-inch Wray equatorial, with a power of 25 on July 22d. 18h. 30m. G.M.T., he saw a nebulous object which was roughly noted as R.A. = 11h. 35m., Dec. = +7° 0′, and reference to various charts and tables elicited the fact that this was not a previously recorded nebula or comet. On the following evening, the same object was doubtfully recorded as 24′ further south and 7′ eastward of its previous position. Feeling satisfied that this was really a new comet, Mr. Grigg acquainted Mr. Baracchi (Melbourne Observatory) and the Press Association of his supposed discovery.

Three days later, and also on August 1 and 2, the same observer again saw the suspected comet and recorded the following positions:—

	d.	h. m.	° ′
July	23·8 G.M.T.	R.A. = 11 40	Dec. = +6 35
	26·8 ,,	,, = 12 0	,, = +5 30
	29·8 ,,	,, = 12 20	,, = +4 20

and from these he calculated the following elements:—

T = June 20, 1902.

$$\begin{aligned} \omega &= 292^\circ\ 43' \\ \Omega &= 217\ \ 48 \\ i &= 18\ \ 24 \\ \log q &= 9{\cdot}7241. \end{aligned}$$

The observations are all of them a little doubtful owing to persistent haze and moonlight, but Mr. Grigg gives the particulars for "what they are worth," and has sent them in this uncertain state in order to catch the outgoing mail.

The position of his observatory is:

Longitude	... ...	175° 32′ 38″·54 E.
Latitude	... ...	37 8 23·21 S.

COMET 1902 *b*.—*Circular* No. 51 from Kiel gives the subjoined elements and ephemeris, as calculated by Herr Elis Strömgren from the observations made at Lick on September 1, at Urania on September 2, and at Copenhagen on September 4, for the comet discovered by Perrine at Lick on September 1.

Elements.

T = 1902 Nov. 23·315 Berlin.

$$\left.\begin{array}{l}\omega = 153\ 53'\cdot 2\\ \Omega = \ \ 50\ 10\cdot 6\\ i = 157\ \ 8\cdot 2\end{array}\right\} 1902\cdot 0$$

$\log q = 9\cdot 60094$.

Ephemeris.

1902.		α app. h. m. s.		δ app. ° ′
Sept. 6	...	3 11 48	...	+37 0·3
10	...	3 4 26	...	+39 10·4
14	...	2 52 59	...	+41 51·4
18	...	2 34 47	...	+45 13·2
22	...	2 4 19	...	+49 23·3
26	..	1 10 1	...	+54 3·8

Perrine describes the comet as "slightly elongated, mean diameter 4′, magnitude = 9, tolerably well-defined nucleus, possesses a tail." Struve, observing at Königsberg on September 2, 10h. 41m.·2 (Königsberg), saw a sharply defined nucleus of the 11th magnitude.

NEW ALGOL VARIABLE.—Mr. A. Stanley Williams announces in the *Astronomische Nachrichten*, No. 3811, the discovery of a new Algol variable (13, 1902 Lyræ), the position of which he gives as

$\alpha = 19$h. 10m. 48s.·7. $\delta = +32°\ 10'\cdot 1$ (1855).

This object is the most following, and normally the brightest, of the three stars forming a small triangle south of the 9·1 mag. star B.D. + 32°·3377. On the scale used, its normal magnitude is 10·98, whilst at minimum it is only just visible with the 6·5-inch reflector, *i.e.* its magnitude is about 12·8.

The star remains at its normal brightness for about 3d. 6h. 22m., and the increase and decrease each occupy about 4 hours; there is no apparent interval at minimum, and the observations, so far, have not indicated the presence of any secondary minimum.

Subjoined is an extract from an ephemeris, calculated for every fifth minimum by Mr. Williams.

1902.				G.M.T. h. m.
Sept. 21	...	...	...	11 28
Oct. 9	...	...	...	11 20
Oct. 27	...	...	...	11 12
Nov. 14	..	...	...	11 4
Dec. 2	...	...	...	10 56
Dec. 20	...	...	...	10 48

Prof. E. Hartwig observed this variable from 9h. 22m. to 11h. 19m. (Bamberg M.T.) on August 16, and found that, during that period, its light decreased by 1·3 magnitudes; cloud and strong moonshine prevented the observations from being carried on throughout the minimum.

SIR DAVID GILL'S NEW THEORY OF STELLAR MOVEMENT.—Mr. Carpenter has recently been examining the measures of the stellar photographs obtained at Oxford during the last seven or eight years, in order to see if they indicate any such movement of the brighter stars as a whole, with respect to the fainter stars as a whole, as was recently suggested by Sir David Gill. Although this was too great a task for Mr. Carpenter to finish during his holiday, he got far enough to find indications which supported Gill's hypothesis.

This result was considered so important that the whole of the Oxford staff was deputed to examine the photographic measures for a belt of stars about Dec. + 26°, and the result indicates that there *is* an apparent movement as suggested amounting to about 0s.·002 per magnitude per year. This corresponds in magnitude to the quantity found by Gill, "*but its sign is opposite to that found by him.*" If this sign is found on further revision to be correct, then it is difficult to imagine that the movement is simply one of rotation, and further investigation must be made before any definite theory may be accepted (The *Observatory*, September, 1902).

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. W. H. MILLS, Fellow of Jesus College, Cambridge, has been appointed head of the chemical department of the Northern Polytechnic Institute in succession to Mr. H. C. L. Bloxam.

MR. H. W. MALCOLM, B.Sc., has been appointed lecturer and demonstrator in physics at University College, Bristol, in the place of Mr. L. N. Tyack.

MR. W. R. KELSEY, late of the Bradford Technical College and of the South-West London Polytechnic, has been appointed principal of the Taunton Municipal Technical Institute.

THE University of Nebraska has this year added a course of study in forestry to its curriculum. The course will extend over a period of four years.

THE sum of 1000*l*. has been placed by Sir Conan Doyle at the disposal of the senatus of Edinburgh University for the purpose of instituting a bursary in the faculty of medicine, available only for students from South Africa. The bursary is to be administered in detail as the University may direct.

Science for September 5 publishes for the fifth year in succession statistics of the conferment of the degree of Doctor of Philosophy by American universities. In the present year, some 214 doctorates have been conferred by twenty-seven institutions, as against 253 in 1901, 233 in 1900, 224 in 1899 and 234 in 1898. The largest numbers of degrees conferred were in the subjects of chemistry, zoology, physics and botany, the numbers being respectively 24, 16, 12 and 11.

SIR HENRY CRAIK'S report for the year 1902 on secondary education in Scotland shows that there has been a large increase in the number of schools presenting candidates in science subjects at the leaving certificate examination, and also in the total number of candidates presented. In many cases there has been a distinct advance in the quality of the work done as compared with former years. It is satisfactory to know that in the examinations of Scottish secondary schools great prominence is given to oral and practical methods of testing the work, and the examinations in the case of each school are shaped by the curriculum of that school.

THE educational announcements for the session 1902–3 of the Northampton Institute, Clerkenwell, make an imposing volume of some 200 pages. Classes will be provided in a large number of technological and trade subjects, but students who require instruction in literary or commercial subjects must go to one of the other City polytechnics, for the Northampton Institute is primarily intended to teach technology. Very properly, great attention is given to subjects which directly assist the industries of the immediate neighbourhood. The courses of instruction fall into two distinct sections, the engineering day classes for students willing to give the whole of their time for one or more years to a systematic training in some branch of engineering, and the evening classes in a variety of subjects for working men engaged during the day.

THE new regulations of the University of Oxford School of Geography show that admission is not confined to members of the University, but all applicants must give satisfactory evidence of sufficient general education to profit by the teaching. A course of instruction in the subjects required for the University diploma in geography begins in October and extends over one academic year. Weekly lectures are delivered by all the members of the staff, six in number, and practical instruction is given on at least four days in each week, and includes position-finding, topographical surveying and map-projection. A scholarship of the value of 60*l*. is offered annually for competition among members of the University who have taken honours in one of the final schools of the University. During 1901–2 the lectures were attended by 208 students, of whom 163 were men from twenty-one colleges, and forty-five women from five colleges or halls.

IN urging the necessity for a more extensive and highly developed system of technical education in this country, English men of science often refer to the provisions made in the United States of America to equip American workers with a practical education of a technical kind so as to fit them to take a useful place in the industries of their country. A recent address, by Prof. V. C. Alderson, Dean of the Armour Institute of Technology at Chicago, on "Technical Education an Economic Necessity," shows some imperfections in the American system. Prof. Alderson is of opinion that up to the present the existing admirable technical institutions in the United States have concerned

themselves only with the needs of the highest grades of workers, "the commissioned officers of our industrial army," as he calls them. "The great mass of non-commissioned officers and privates are left uncared for." The region of what may with approximate correctness be called "secondary technical education" is represented in the United States, Prof. Alderson says, "by more or less feeble efforts in a few trade schools, in a limited number of private institutions aimed to help the working men and in night schools." American educational authorities are urged, later in the address, to follow the example of Switzerland, and, "recognising the dependence of national prosperity upon technical education, to set about the task of providing an education for all classes of workers suited to their callings. The technical high school, if properly equipped and put in close relationship with the trades and industries, will satisfy this national need; it will not be a copy of the European trade school, but rather an adaptation of the trade school which will be in harmony with American thought and American educational ideals."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 8.—M. Bouquet de la Grye in the chair.—The president announced to the Academy the death of M. R. Virchow, Foreign Associate of the Academy.—Address by M. Bouchard on the occasion of the death of R. Virchow.—On the irreducibility of uniform transcendentals defined by differential equations of the second order, by M. Paul Painlevé.—The experimental study of the resistance to compression of armed mortar, by M. Considère. A study of the mechanical properties of prisms of cement having embedded in its mass metallic wires of various shapes. The results are summarised in a graphical form.—On the eruption of Martinique, by MM. A. Lacroix, Rollet de l'Isle and Giraud. In discussing the calorific and physiological effects of the eruption in the town of St. Pierre, all the observations indicate the rapid and persistent action of a source of heat at a high temperature, producing asphyxia. In a central zone the temperature was sufficiently high to determine combustion, to superficially carbonise the bodies after burning their clothes, but it was insufficient to melt thin copper wires, or below 1054° C. On the edges of this zone the phenomena of asphyxia continue, but the temperature was hardly high enough even to char the clothes. The presence of steam and ashes in the destructive cloud which overwhelmed the city is certain; the presence of combustible gases such as hydrogen sulphide, hydrocarbons or hydrogen cannot be proved with certainty, but such a supposition would explain many of the effects produced. The commission consider the complete evacuation of the entire neighbourhood of Mont Pelée is imperative, and must be maintained until the complete cessation of the volcanic disturbances.—On the secular acceleration of the mean longitude of the moon, by M. H. Andoyer.—The comet 1902 *b*, discovered on September 1 by M. Perrine and independently by M. Borrelly, September 2, at the Observatory of Marseilles. Observations made by MM. Borrelly and L. Fabry.—Observations of the comet 1902 *b*, made at the Observatory of Besançon, by M. P. Chofardet.—On certain differential equations, by M. Edmond Maillet.—On the properties of closed chambers relating to electric waves, by M. A. Turpain.—On a new acidimetric indicator, by M. L. J. Simon. By the dry distillation of tartaric acid with potassium bisulphate, a new acid isomeric with pyrotartaric acid has been obtained the ferric salt of which may be used as an indicator. It possesses the curious property of giving similar indications to a mixture of methyl-orange and phenolphthalein, and in some cases conveniently replaces such a mixture.—On the interrenal bodies of Plagiostomes, by M. Ed. Grynfeltt.—On some india-rubber plants on the west coast of Africa, by M. Aug. Chevalier.—On the duration of the germinating period in seeds exposed to sunlight, by M. Victor Jodin.

NEW SOUTH WALES.

Linnean Society, July 30.—Mr. J. H. Maiden, president, in the chair.—Descriptions of some new species of plants from Western Australia, by Mr. W. V. Fitzgerald. Five additions to the flora of Western Australia referable to the genera Mitrasacme, Cremnophila, Grevillea and Schœnus (two species) are described.—Descriptions of new species of Queensland Lepidoptera, by Dr. Thomas P. Lucas. Two genera and five species, distributed among three families (Cossidæ, Pyralididæ and Xylorictidæ), are described as new.—A revision of the genus Notonomus (fam. Carabidæ; subfam. Feronini), by Mr. Thomas G. Sloane. Seventy-two species are attributed to the genus, twenty-seven being described as new.—Contributions to a knowledge of Australian Entozoa. No. ii. On a new species of Distomum from the sawfish-shark (*Pristiophorus cirratus*, Lath.), by Mr. S. J. Johnston. The worm has an extremely mobile neck in the living state. Its most characteristic features are its size, the character and position of the suckers, the folded but unbranched limbs of the intestine, the grape-like vitelline glands and the very marked development of the excretory system. It falls into Dujardin's subgenus Brachylaimus.—Notes on Australian Lycænidæ, by Mr. G. A. Waterhouse. *Lycaena nigra*, Misk., is referred to the genus Megisba, Moore. *Holochila purpurea*, Grose-Smith and Kirby, is given as a synonym of *H. cyprotus*, Olliff. *Holochila androdus*, Miskin, and *H. subargentea*, Grose-Smith and Kirby, are given as synonyms of *H. helenita*, Semper. The sexes of *Ogyris oroetes*, Hew., and *O. amaryllis*, Hew., are described; likewise two new species. The paper concludes with a note on *O. ianthis*, Waterh.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part 4 for 1902, contains the following memoirs communicated to the Society:—

November 8, 1901.—David Hilbert: On the bases of geometry.

May 3, 1902.—Ernst Richard Neumann: New integral properties of successive potentials. W. Voigt: On the absolute retardation of light-waves on reflection.

The accompanying *Proceedings* include reports on the progress of the "Mathematical Encyclopædia" and the publication of Gauss's works; obituary notices of Friedrich Leo, Adolf Erik von Nordenskiöld, Karl Hegel; and congratulatory addresses to Eduart Süss, of Vienna, and Dedekind, of Brunswick.

CONTENTS.

THURSDAY, SEPTEMBER 25, 1902.

LEGENDS OF PALESTINE AND ARABIA.

Theology and Ethics of the Hebrews. By Archibald Duff, M.A., LL.D., B.D., Professor of Old Testament Theology, Yorkshire College, Bradford. Pp. xvii + 304. (London: John C. Nimmo, Ltd., 1902.)

Syria and Palestine. By Lewis Bayles Paton, Ph.D. With Five Maps. Pp. xxxvi + 302. (London: John C. Nimmo, Ltd., 1902). Both in the "Semitic Series." Each 5*s.* net.

THE increasing number of popular books on early Semitic history and sociology marks the ever-widening interest taken in this branch of scientific research, especially as far as the results of modern Old Testament criticism are concerned. The writer of a popular handbook undertakes a serious responsibility; it is for him to weigh carefully the arguments for and against all important theories, and to set before the general reader a fair and unbiassed account of what he considers to be the certain and indubitable results of the labours of scholars. In all matters of Biblical criticism he must hold a middle course between the servile acceptance of traditional belief on the one hand, and a system of drastic and monotonous emendation on the other. Above all must he keep himself severely aloof from ephemeral hypotheses, for he is writing for the uncritical layman and not for the discriminating expert.

Dr. Duff's book on the theology and ethics of the Hebrews seems hardly to fulfil all the above requirements. The first section opens with the period of Hebrew history which begins with the fifteenth century B.C., and describes the Exodus from Egypt to Sinai. Then follows what is, to say the least of it, an unsatisfactory explanation of the episode of the Tables of the Law. According to Dr. Duff, "then or thereabouts two slabs were brought down from the heights. There were strange markings upon them, crystalline, fossil, or otherwise" (p. 9). Of the three possibilities, the last is certainly the most probable, as neither crystalline nor fossil markings are likely to be mistaken for writing, and as the mountain traditionally regarded as Sinai is of granite, it is hardly probable that fossils would be found there. However, Dr. Duff proceeds with his explanation: "There arose in time a sacred formula connected with this relic, whereby they called their god

"'The Almighty Yahweh who sits
Throned upon the winged creatures.'

"This seems to suggest that the seeming hieroglyphic figures on the slabs were fossils or else crystalline forms resembling winged creatures. Therefore the people called them 'Kroobs,' *i.e.* Griffins (Γρύψ)." The connection of Dr. Duff's "Kroobs" (which in the traditional transliteration is *cherub*) with Γρύψ, has been given up by the Oxford Hebrew Dictionary (Clarendon Press, 1892, p. 500). That such supposed fossil markings on granite could be mistaken for "hieroglyphic figures," or crystalline markings for "winged creatures" or "Kroobs," are explanations harder to understand than the difficulty which they are devised to solve.

Dr. Duff inclines to the opinion that the divine name, Yahweh, is a causative incipient from the root *hawah*, *i.e.* the god who caused rain to fall and thereby brought life and all things into being (p. 11). This is certainly possible, and appears to be as good an explanation as the other plausible view that Yahweh is the Kal of *hawah* (= *hayah*), *i.e.* "He Who Is."

When Dr. Duff reaches the third part of his book, wherein he describes the teachings of the prophets, he stands on firmer ground, and appears to know his subject better. Naturally, he begins with the caustic utterances of Amos against the luxury of Israel, and his warnings of the Assyrian approach; and, with the exception of a passage of "fine writing" on the first page, his *résumé* of this prophet is a good one. In the chapter on Hosea, which follows, the author has apparently been unable to make up his mind about a theory which, if it were true, would profoundly modify our conception of early Arabian and Hebrew history. On p. 61 he says: "Events on the Upper Nile or in Arabian muçur (*sic*) now left a southern prince So or Sewe (Sabako?) free to turn again to plots in the Asiatic direction"; but, in spite of this leaning towards the heresies of Dr. Winckler, the author inclines to the more usual view of the relations between Israel and Egypt at this time. He is certainly to be congratulated on not having gone over entirely to what on the face of it seems a possible theory, but which in reality has less in its favour than is at first sight apparent.

Taken as a whole, Dr. Duff's book will be found useful, and though the author's style is at times somewhat tedious, his matter has been well arranged, and the idea of the analysis of the "J" and "E" portions of the Old Testament at the end is an excellent one.

In the second of the two books under review Dr. Paton has endeavoured, as he says in his introduction, to "gather up the results of the most recent explorations, and combining them with the facts already known from the Bible and from other ancient sources, to present them in a clear and popular form." His book deals with the history of Palestine and its relations with Egypt and Mesopotamia from the earliest times down to Cyrus, and to this end the author has laid under contribution a large quantity of material both from Egyptian and Assyro-Babylonian sources, though apparently he has little first-hand knowledge of the original texts. A wider understanding of the languages of the peoples with which he deals would have prevented him from falling into certain errors that are to be found in his book. For instance, he has adopted the chronological system of Lehmann, and although he accepts Assurbanipal's dating for Kudurnankhundi, who invaded Babylonia 1635 years before Assurbanipal's time (p. 30), yet, apparently only on the ground of its extreme antiquity, he rejects Nabonidus's date for Naram-Sin, who is said by the former to have reigned 3200 years before (p. x.). Again, he seems unable wholly to accept the truth about the "Chedorlaomer" texts, and sums up his review of the facts with the words, "It still remains doubtful, therefore, whether Chedorlaomer is mentioned in the

Babylonian monuments" (p. 34). Now, as the "Chedorlaomer" myth was long ago exploded by King ("Letters and Inscriptions of Hammurabi," vol. i. p. xxv.), there is no longer any question about this matter, at any rate so far as the tablets that have been discovered up to the present time show. Noticeable, also, is the translation of "Ya'aqob-el" and "Yoseph-el" as "Jacob-god" and "Joseph-god" (p. 42), which is misleading to the general reader, and almost seems to betray in the author an ignorance of the meaning of these names. Further, "Moriah" is hardly likely to be the equivalent of the Sumerian MAR.TU (p. 16).

In this book we again meet with the "Arabian-Muṣri" theory, though even its supporters do not seem to be very certain as to where they intend to fix the position of their hypothetical Muṣri. Even in the two maps where it is marked the position assigned to it is not the same in the one as in the other, and it has therefore apparently been given what is known mathematically as a *locus* in which its position varies, at one time shifting perilously near the borders of the southern Muṣri, *i.e.* Egypt (pp. 157 and 200). Since this so-called "epoch-making" theory has now begun to be reproduced in popular works, it is but right that the arguments on which its supporters rely should be examined in detail.

In 1893[1] Dr. Winckler published a theory that in addition to the two countries called in the Assyrian inscriptions Muṣri (Egypt and part of Northern Syria) there existed a third in Northern Arabia, and since then he has adduced a number of arguments in order to support this theory, both from the Assyrian and Himyaritic inscriptions. Among German scholars it has received little encouragement, but in England Dr. Winckler has been fortunate in finding an eloquent and receptive advocate in Prof. Cheyne, who has given it his sanction in the "Encyclopædia Biblica."[2] Since a popular handbook has absorbed and given credence to what is considered by the majority of critics to be a doubtful question, to say the least of it, it will be as well to state Dr. Winckler's arguments *seriatim*, in order that we may see how far they bear out his case. They may be briefly enumerated as follows :—

(1) Tiglath Pileser III. appointed a certain Idibi'ilu to be *ḳîpu* over Muṣri,[3] and this Idibi'ilu is mentioned elsewhere in the inscriptions of the same king,[4] where he is called "Idibi'ilu of Arubu" (*i.e.* Arabia). Hence, Dr. Winckler says that Muṣri cannot mean Egypt here, but is a country in Northern Arabia, apparently simply because Idibi'ilu was an Arab. Now there seems to be no reason for translating Muṣri as anything else than Egypt, for the Assyrians at this period were pushing their dominions rapidly down through Palestine. Further, we are not told that Tiglath Pileser conquered Egypt, but only that he appointed an Arabian sheikh as *ḳîpu* (an officer whose duties were obviously to watch the marches), a most natural and proper person for this purpose. So the new Muṣri theory receives no support from the first hypothesis.

(2) Yamani,[5] the leader of the revolt in Ashdod, flees

[1] *Altorientalische Forschungen*, i. 24.
[2] iii. 3161.
[3] *Annals*, l. 226, &c.; Winckler, *Altor. Forsch.*, i. 25.
[4] *Annals*, l. 240.
[5] Winckler, *Sargon*, Pr. l. 102; *Altor. Forsch.*, i. 27.

before the approach of Sargon *ana ite* (*mâtu*) *Muṣuri ša paṭ* (*mâtu*) *Meluḫḫa*, *i.e.* to the side of Muṣuri which borders on Meluḫḫa.[1]

If Meluḫḫa be "Sinai, Midian," as Dr. Winckler at first supposed,[2] there is no reason to assume that Muṣuri is a country lying to the east of this district, for if Muṣuri be translated "Egypt," such an identification entirely agrees with the Assyrian geographical description of the southern Muṣri. Besides, the most natural route for Yamani, who was fleeing from Ashdod before the Assyrian army advancing through Palestine from the north, led straight into Egypt, and not into Arabia, directly across the enemy's line of advance.

(3) Dr. Winckler argues that the Pir'u (spelt with the determinative prefix of persons and not officials) mentioned in the Assyrian texts[3] is not Pharaoh, as Schrader supposed, but the proper name of a sheikh of his North Arabian Muṣri, since he is once spoken of as *malku*. But Pir'u is certainly called *šarru* in the same inscription, so this cannot be considered of any great importance. It was about this time that the Assyrians of the later Empire were coming into actual contact with the Southern Muṣri. Tiglath Pileser III., who pressed as far as its borders, mentions no king by name, but Sargon speaks of its king as Pir'u, evidently understanding it as a proper name. Now, we have an exact parallel to this in the Old Testament, where the Hebrews first speak of the King of Egypt as Pharaoh, evidently understanding it as a proper name, but later mention him either by name (Shishak), or with the addition of the royal title (Pharaoh-Necho, Pharaoh-Hophra). Further, in the last of the three texts quoted below in note [3], there is surely no doubt that Haziti is Gaza, Rapiḫi is Raphia, and Sib'i is So (= Sēwē); and, these being granted, there is little to be gained by inventing an Arabian Muṣuri, when "Egypt" is the obvious explanation of the name. From this third line of argument, therefore, the new theory obtains no support.

(4) In the account of Sennacherib's battle at Eltekeh,

[1] It is doubtful whether any such meaning as "included in" or "belonging to" can be safely attached here to *ša paṭ*. Dr. Winckler's additional examples carry no weight (footnote, AOF, i. 27); the first, "Aphek im gebiete der provinz Samaria," rests on a misreading of *Sameri[na]* for *Samena* . . ., or much less probably *Sameru*. . . . This name was copied *Samena* . . . by Dr. Budge in his *Esarhaddon*, 1880, p. 119, in correction of W. A. I., iii. and TSBA, iv., but this correction is totally ignored by Winckler (*Untersuchungen*, 1889, p. 98), who repeats the old mistake *Samerina*, and apparently did not recognise it until his publication of *Muṣri, Meluḫḫa, Ma'in* (1898, p. 8). Dr. Budge's translation, "Apheḳ, which borders on the country of Samena," still holds good, inasmuch as no suitable identification for Samena has been suggested (Winckler's later suggestion, *Shimeon*, being doubtful). Even if it were Samaria, the translation "On the borders of Samaria" would quite agree with the geographical position of Aphek. His second example is "Pillatu ša paṭ Ilamti Tigl. 14 (i R 67)" (read "Pillutu ša patti Ilamti Tigl. 14 (ii R 67)"). As we do not know the exact locality of Pillutu, it is impossible to base any theories on the meaning of *ša paṭ* here, for the city in question may have been on the border of Elam.

[2] *Altor. Forsch.*, i. 27. We shall refer to Dr. Winckler's later theory that Meluḫḫa = Yaman further on.

[3] *Muṣri, Meluḫḫa, Ma'in*, 1898, p. 2. *Cf.* (a) "Philistia, Judah, Edom and Moab . . . had brought presents to Pir'u, king (*šar*) of Muṣri, a chief (*malku*) who could not save them." (b) "Of Pir', king of Muṣuri, Samsi, queen of Aribbi It'amra of Saba'ai, kings of the side of the sea and the desert . . . their tribute I received." (c) "Ḫanunu, king of Ḫaziti, with Sib'i the tartan of Muṣuri to the city of Rapiḫi to battle came against me; their defeat I accomplished. Sib'i feared the clash of my weapons and fled away, and his place was no more seen. Ḫanunu, king of Ḫaziti, in hand I captured. The tribute of Pir'u," &c.

Dr. Winckler[1] considers the Muṣur, which is here mentioned with Meluḫḫa as coming to the help of the Ekronites, to be the so-called North Arabian country, and not Egypt. But Egypt was the natural ally of Palestine, and there is no reason to suppose that the Muṣur here mentioned is anything else but Egypt, especially as the scene of the battle was Eltekeh, which is either in or near Philistia.

(5) Dr. Winckler finds support for his Arabian Muṣri[2] in a Himyaritic text (Glaser, 1155 = Halévy, 535) which mentions *Mṣr*, *'Aŝr*, *'ebr nhrn*,[3] and *Mdi*. 'Aŝr is mentioned elsewhere in the Himyaritic inscriptions (Glaser, 1083). The former of these inscriptions was assigned by Hartmann[4] to the year of the conquest of Egypt by Cambyses (525 B.C.), and there is little doubt that this dating is correct. *Mṣr* undoubtedly refers to Egypt; *Mdi*, of which Dr. Winckler gives no explanation, is, as far as we can judge at present, Media; while the identification of *Aŝr* is as yet uncertain. Hartmann has shown that the speculations of Hommel as to the possibility of this inscription dating back to the time of the eighteenth Egyptian dynasty (*c.* 1500 B.C.) are without foundation, and the same may be said for the theory promulgated by Dr. Winckler, according to whom this text gives a hint of the wars of the people of Ma'în (= Meluḫḫa) and its supposed northern dependency, his imaginary Muṣri, against the Assyrians in Southern Palestine in the eighth century B.C.[5] The explanation of Hartmann is entirely sufficient; and no proof of the existence of an Arabian Muṣri can be found in the Minæan inscriptions. It may be noted that Dr. Winckler does not accept the obvious meaning of the term *'ebr nhrn*, "across the river," *i.e.* in the eyes of the Arabs Persia, an explanation which entirely fits in with Hartmann's chronological theory.

(6) Dr. Winckler, however, has finally brought forward evidence which, on the face of it, seems good. He maintains that the small fragment of Assyrian tablet 83-1-18, 836 (which mentions Esarhaddon) proves the existence of Muṣri as distinct from Miṣri, *i.e.* Egypt. It

"wird durch seine nebeneinandernennung von Muṣri und Miṣri d.h. von unserem Muṣri und Ägypten," he says, "ja wol wenigstens die auseinanderhaltung beider länder von nun an bewirken,"

and he has attached such importance to it that he has published it in full.[6] Unfortunately, besides one or two other bad blunders[7] in a small text of six fragmentary lines, he has misread the one sign which was of importance to his theory.

In the fourth line Dr. Winckler reads, . . . mâ]tu Mu-us-ri u mâtu Mi-iṣ-[ri . . . , thus proving to his own satisfaction that Musri and Miṣri were two distinct countries. But the *iṣ* in Mi-iṣ-[ri] ends at the break in the clay, and even from the very slight traces that remain, it is certain that the character is not *iṣ*. Taking into consideration the common conjunction of the country *Miluḫḫa* with Muṣri, so well known to Assyriologists, there can be no possible doubt that the sign was originally *luḫ*, and not *iṣ*, and the slight traces that remain (the traces of the top of another vertical wedge) make this hypothesis a certainty. Thus Dr. Winckler's attempted proof of a mention in Assyrian literature of a Musri side by side with Miṣri (Egypt) falls to the ground.

Dr. Winckler has therefore furnished no proof whatever of the existence of a North Arabian Muṣri, and until he does so, it is impossible to believe in the existence of a Muṣri other than Egypt and the well-known country in Northern Syria.

Apart from these matters, Dr. Paton has evidently spent much time and trouble on his book, and although he has been influenced in too great a degree by the school of Hommel, his compilation will probably be found useful. Both Dr. Paton and Dr. Duff have added an excellent index to their books, and if only they had had a wider acquaintance with the languages of Assyria and Egypt, they would probably have been able to speak in less uncertain tones of the results obtained from the study of cuneiform and hieroglyphic texts. OUR BOOK SHELF.

The Elementary Principles of Chemistry. By A. V. E. Young. Pp. xiv + 252 + 106. (London: Hirschfeld Brothers, Ltd., 1902.) Price 5*s.* net.

THIS book, which is of American authorship, provides an elementary course of inorganic chemistry based upon the quantitative system. There is a theoretical part, an experimental part, and an appendix giving hints on manipulation. The student is to perform the experiments, make notes, and then to turn to the theoretical part for fuller information on the topic of his experiments, the teacher supervising each portion of the work.

The author expresses the hope that his book will contribute "to making practicable and serviceable that which he enthusiastically believes is both scientifically and pedagogically an improvement on the older and still largely prevailing method." An examination of the book leads to the belief that this hope will be fulfilled, for there can be no doubt that the author is imbued with real educational zeal, and that he has bestowed much care and thought upon the arrangement of an excellent sequence of experiments illustrative of the main principles of chemistry. A. S.

P.O.P. (*The Use of Silver Printing-out Papers*). By A. Horsley Hinton. Pp. 134. (London: Hazell, Watson and Viney, Ltd., 1902.) Price 1*s.* net.

SILVER printing-out papers are now so extensively used that a small volume like this cannot fail to be useful to a large number of those who practise photography. There is nothing particularly original in it, but a practical and successful photographer like the author cannot set down a series of instructions without giving many a useful hint. Current photographic literature and manufacturers' "instructions" furnish an almost endless variety of formulæ for the treatment of printing-out papers; it will therefore be distinctly advantageous to those whose experience of such papers is not large to have a small collection of selected formulæ such as is here given. The illustrations that show the extent of over printing necessary to compensate for the loss by toning and fixing, and the kind of negative best suited for these processes, will be very welcome to the beginner. It would have been but little trouble to provide an index, the advantage of which in a book of practical instructions it is not necessary to point out.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Symbol for Partial Differentiation.

IN his first letter (p. 53), Prof. Perry very properly drew attention to the desirability of greater definiteness in the notation for partial differential coefficients in the case of functions of two variables, the essence of his remarks being that it is not enough merely to change d into ∂, but that the variable which is for the nonce held to be constant should also be indicated. Apropos of this, and for the sake of historical interest, I quoted from a paper since published (*Proc.* R.S. Edinb xxiv. pp. 151–194) a short paragraph regarding a passage[1] in Jacobi's writings of the year 1841, and containing a footnote with an old suggestion on the matter of notation. In his second letter (p. 271), Prof. Perry undertakes to show that this latter notation is objectionable so far as thermodynamics is concerned, and not to be compared with that which he himself uses. I regret to have to say that I was quite satisfied with his notation, and had no intention whatever of bringing the two into comparison, mine having been designed for much more complicated cases than those which occur in ordinary text-books on thermodynamics. His words are:—

"I use one letter E where on Mr. Muir's suggestion I must use six distinct symbols if I have to express any differential coefficient of E, and if I have to express all the differential coefficients of v I must use other six symbols; altogether I must use thirty of these curious symbols instead of five common letters, and, furthermore, I must keep them all in my head."

This is, of course, all a mistake. Without any desire, therefore, to spare Prof. Perry's head, but merely in order to undo a misrepresentation, however unwitting, I am forced to point out that if we are to have a perfectly definite notation in this connection, we must indicate three things, viz. (1) the dependent variable E; (2) the two independent variables, say v and p; and (3) whether the differentiation is to be performed with respect to v or p. Now, in the notation of my last letter these three are all cared for, thus

$$E_{\overline{\overset{1}{v}, p}};$$

or, since a vinculum contributes a "curious" look to the symbol, let it be written

$$E\,(\overset{1}{v}, p).$$

The notation used by Prof. Perry, viz.

$$\left(\frac{dE}{dv}\right)_p$$

is a trifle lengthier, but, as I have said, is equally definite, the main difference between the two arising from the fact that in the matter of differentiation he is a "dee-ist"; it is, however, excessively cumbrous when used in the complicated cases for which the other was designed.

THOMAS MUIR.

Cape Town, South Africa, August 9.

IT would have been presumption on my part to express my private opinion, which is in favour of Dr. Muir's symbol in general mathematical work, and so I referred merely to its use in thermodynamics where I think that such a use would be bad.

The form he now gives is handier, being a mnemonic for my symbol, but I submit that it is different from what he would use in other applications of mathematics. According to his general system, $p\,(\overset{1}{v}, \phi)$ implies that there is a function of v and ϕ called $p\,(v, \phi)$ which is differentiated. But $p\,(\overset{1}{t}, E)$ implies that there is a function $p\,(t, E)$, and in thermodynamics $p\,(v, \phi)$ is always equal to $p\,(t, E)$. If p is a functional symbol there can be no such equality, and I still think that the forms in which I put Dr. Muir's suggestion were the only ones consistent with his instructions. The new form would give no great trouble to a good mathematician perhaps, but it would quite unsettle the ordinary student of thermodynamics.

A man who insists on "dee-ism" in those parts of higher mathematics where it is clumsy is an obstacle to progress. But if Dr. Muir had my experience in dealing with men who know only a little mathematics and who wish to use what they know, he would, I think, be a "dee-ist" in elementary work.

JOHN PERRY.

[1] Well worth reading. It begins at "Ut distinguerentur," on p. 320, and ends at bottom of p. 322 of vol. xxii. of *Crelle's Journal*.

PROF. JOHN JAMES HUMMEL.

JOHN JAMES HUMMEL was born in 1850 at Clitheroe, in Lancashire. His father was a native of Switzerland and his mother English.

His scientific education was obtained at the Zurich Polytechnic, where he studied under Bolley, Städeler, Wislicenus and Weith. On returning to England in 1870, he became chemist in the calico printworks of Messrs. Jas. Black and Co., of Alexandria, near Glasgow, and remained there six years, busily and successfully engaged with new dyeing problems incident to the introduction of artificial alizarine and other coal-tar dyes. He was subsequently connected with other printing and dyeing firms, until in 1879 he decided to gratify his taste for science and teaching by applying for the post of Instructor in the dyeing department established at the Yorkshire College by the Clothworkers' Company of London. On taking up work at the College, Hummel applied himself with the utmost assiduity to devising and developing a system of instruction in dyeing. In this difficult undertaking he relied upon his own ideas, and he will always rank as a pioneer in this branch of teaching. He was a firm believer in the value of pure science, and always protested against that superficial teaching of technology too often attempted in compliance with the wishes of self-styled practical men. The course of teaching which he devised has been adopted very widely in this country and has attracted much attention abroad. The Dyeing School at the Yorkshire College has drawn students from all parts of the world.

Hummel's original contributions to his subject have always been marked by mastery of the subject in hand and scrupulous attention to detail. The burden of teaching and administrative duties severely restricted his time for experimental investigations, but his desire to have such work in progress in his department was gratified in the most handsome way by the Clothworkers' Company, which has associated a research chemist with the professor of dyeing.

The last few years of Hummel's life were devoted to the planning and organisation of important extensions of his department, which is now in possession of extremely ample and well-appointed buildings. In this, as in all other work, Hummel did not spare himself, and the strain doubtless told upon his health.

As an expert on his subject, Hummel was in constant demand. He lectured occasionally on important developments of dyeing before the Society of Arts, the Imperial Institute and other institutions, and he was a juror at the last Paris Exhibition. As an author, he was best known by his admirable text-book of dyeing, which has had a very large circulation and has been translated into a great variety of languages.

His labours have done much for the college with which he was associated and for the important industry that he so earnestly desired to serve. Fortunately, he has left a large number of disciples who, in different parts of the world, are carrying on the work which he originated.

A. S.

THE BRITISH ASSOCIATION AT BELFAST.

THE Belfast meeting of the British Association was concluded as we went to press last week. The weather during the meeting was not all that might have been desired, but both the local committee and the visitors have reason to be thankful that the deluge which flooded Belfast a few days before the opening meeting did not occur a few days later.

The flags of the presidents were in imminent danger of destruction on account of this flood. They had been placed on a table in the Grosvenor Hall ready to be hung up for the opening address, and were saved only by the timely action of the Rev. Mr. Kerr, who divesting himself of some of his clothing, waded in to their rescue. The water afterwards rose to a height of several feet in the Hall, an occurrence never before experienced there.

With the exception of the garden party given by the local executive committee in the Botanic Gardens Park, when the rain came punctually at the hour named on the cards and departed with the guests, all the other outdoor functions went off with nothing more than a sprinkle or two.

The garden parties of the Earl and Countess of Shaftesbury and of Lord and Lady O'Neill at their picturesque residences were favoured with dry but cool afternoons, as was also that of Mr. and Mrs. J. Brown. This last included a visit to the linen factory of Mr. G. Herbert Brown, and an inspection of Mr. Brown's physical laboratory and of various applications of electric power to domestic appliances, among which an electrically driven lawn mower and the ice-making, knife-cleaning and meat-chopping machines in the kitchen offices seemed to attract most attention. The excursions arranged for Saturday were well attended, as also were those planned by the Belfast Naturalists' Field Club for the Thursday after the meeting.

General and warm approval has been expressed regarding the arrangements made by the local officials for the reception and comfort of the members, and although these were smaller in number than on the last occasion, this was not due to any falling off in those visiting Belfast, but rather to the apathy of local people, judging by the smaller number of associates' and ladies' tickets issued, as shown by the following table :—

	1874.	1902.
Old Life Members	162	243
New ,,	13	21
Old Annual Members	232	314
New ,,	85	84
Associates	817	647
Ladies	630	305
Foreign Members	12	6
	1951	1620

It has been questioned whether this falling off, especially in the number of ladies' tickets, may not be ascribed in a considerable degree to the educational methods of Ireland and their effect on the tastes of those brought up under their influence within the last thirty years.

The educational note struck in the admirable Presidential Address of Prof. Dewar seemed to ring through the entire proceedings, and not only in the new Section devoted to the subject, but in joint discussions, and notably in the excellent address of Prof. Perry in Section G, do we find this question prominent. New opinions seem to be growing, and among these are the ideas that the English public-school system must be relegated to the limbo of inefficiency and that the technical school of the kind made in Germany is all very well over there, but almost useless here.

From a scientific point of view, the meeting was without doubt an admirable one. Many important papers were brought before the sections.

At the concluding meeting of the Association, the following votes of thanks were unanimously adopted :—(1) To the Lord Mayor and Corporation for their reception of the Association ; to the President and Council of the Queen's College, the Presbyterian College, the Methodist College and the Elmwood Presbyterian Church for the use of rooms ; and to the Harbour Commissioners for their reception. (2) To the local secretaries—Mr. John Brown, Mr. Ferguson and Prof. Fitzgerald—Dr. Kyle Knox (the local treasurer) and the local committee for the excellent arrangements made for the reception of the Association in Belfast. (3) To the noblemen, gentlemen and public bodies who have entertained the Association ; to the firms who have opened their works ; to the citizens who have hospitably entertained members ; to the gentlemen who have contributed to the success of the excursions ; to the committees of clubs, libraries and other institutions who have opened their premises to the members of the Association ; to the Belfast Tramway Company ; and to the Belfast Press, for their admirable reports of the proceedings.

A noteworthy event of the meeting was the speech given by Prof. C. S. Minot, President of the American Association, in which he invited members of the British Association to attend the meeting to be held early next January at Washington. Prof. Minot said he had been directed by the council of his Association to express the hope that as many members as possible of the British Association would attend the Washington meeting. A vote had been passed to the effect that all members of the British Association would be received upon presenting themselves at the meetings in America as members of the American Association without further requirement. In future, as has already been announced in these columns, the annual meetings of the American Association will begin on the first Monday after Christmas and extend throughout the week. The scientific societies affiliated with the Association have agreed to this arrangement, and the universities have consented to the establishment of this "Convocation Week," in which the meetings of scientific societies are to be held. It is expected that the first meeting to be held next January under this rule will be the most important scientific gathering ever held in America. In the course of his remarks, Prof. Minot said :—

It was the duty, he believed, which they should all perform to attend these gatherings and take part in international intercourse. Many Americans had come to the British Association, and they had always been treated with the greatest hospitality. They arrived strangers and went away friends; they brought expectations, and took back realisations and a grateful memory. He asked for one moment in which to remind them of a new historic condition never existing in the world before. It was the first time that two great nations existed with a common speech, a common past, a common history ; would they not therefore so work together that they might build up a common future? And for the scientific man this duty came first. Each nation was governed, not by the Government, but by the men of learning and above all by the universities. Nowhere, he believed, in the Anglo-Saxon world had science yet taken its place in the universities. Nowhere in the Anglo-Saxon world had the full value of scientific knowledge throughout the whole range of life, from the university down to every practical affair—nowhere, he said, had the full power of the world of science been established.

Prof. Dewar, in replying on behalf of the Association, said :—

They were all delighted to hear the kind invitation which had been extended to the members of the Association by their brother workers on the other side of the Atlantic. The great blunder we in the United Kingdom were perpetrating for many years past was in remaining ignorant of what was being done on the other side of the Atlantic. He had again and again said to manufacturers and those interested in industrial progress that if they would subsidise their chief officials by a donation which would enable them to spend their short holiday by going to see what

could be seen during a three weeks' residence in the United States, to note how they economise time there, how a person could be transferred from place to place, the freedom with which one is allowed to see the great internal organisation—if they did that they would be repaid one-hundredfold. He did not know of anything that had occurred to himself personally which had affected him so much as a short visit which he had the honour of paying to America. Both in the universities and in applied industries it was a revelation to him, and he was sure it would be a personal gratification to every member of that Association, and an entirely new revelation to them, if they took advantage of the invitation offered. He hoped some of the officials of the British Association would be present on the great occasion in Washington.

In bringing the meeting to a close, Prof. Dewar referred to the work of Joseph Black, Thomas Andrews, James Thomson, Lord Kelvin and Prof. Tait, who were connected with Belfast and had given it a leading place in scientific history.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY PROF. G. B. HOWES, D.Sc., LL.D., F.R.S., PRESIDENT OF THE SECTION.

The Morphological Method and Progress.

IT is now twenty-eight years since this Association last assembled in Belfast, and to those present who can recall the meeting the proceedings of Section D will be best remembered for the delivery of an address by Huxley "On the Hypothesis that Animals are Automata, and its History," one of the finest philosophic products of his mind. At that date the zoological world was about to embark on a period of marked activity. Fired by the influence of the "Origin of Species," which had survived abuse and was taking immediate effect, the zoological mind, accepting the doctrine of evolution, had become eager to determine the lines of descent of animal forms. Marine observatories were in their infancy; the *Challenger* was still at sea; the study of comparative embryology was but then becoming a science; and when, reflecting on this, we briefly survey the present field, we can but stand astonished at the enormity of the task which has been achieved.

Development has proceeded on every hand. The leavening influence, spreading with sure effect, has in due course extended to the Antipodes and the East, in each of which portions of the globe there has now arisen a band of earnest workers pledged to the investigation of their indigenous fauna, with which they are proceeding with might and main. Of the Japanese, let it be said that not only have they filled in gaps in our growing knowledge, for which they alone have the materials at hand, but that, with an acumen deserving the highest praise, they have put us right on first principles. I refer to the fact that they have shown, with respect to the embryonic membranes of the common chick, that we in the West, with our historic associations, our methods and our skill, contenting ourselves with an ever-recurring restriction to the germinal area, have, by an error of orientation, missed an all-important septum, displaced under an inequality of growth.

Those of us who have lived and worked throughout this memorable period have had a unique experience, for never has there been progress so rapid, accumulation of observations so extensive and exact. Of the 386,000 living animal species, to compute the estimate low, every one available has been lain under hand, with the result that our annual literary output now amounts to close upon 10,000 contributions, the description of new genera and subgenera, say 1700. More than one-half of this vast series refers to the Insecta alone; but notwithstanding this, the records of facts of structure and development, with which most of us are concerned, now amount to a formidable mass, calculated to awe the unlettered looker-on, to overwhelm the earnest devotee, unless by specialising he can secure relief. As an example of what may occur, it may be remarked that a recent exploration of the great African lakes has resulted in the discovery of over 130 new species.

As to the nature of this unprecedented progress, it will suffice to consider the Earthworms. In 1874 few were known to us. An advance in our knowledge, which had then commenced, had made known but few more which seemed likely to yield result. Darwin's book upon them had not appeared. Some were exotic, it is true, but no one suspected that a group so restricted in their habits could reveal aught beyond a dull monotony of form and structure. Never was surmise more wide of the mark, for the combined investigations of a score of earnest workers in all parts of the world have in the interval recorded some 700 odd species of about 140 genera. Mainly exotic, they exhibit among themselves a structural variation of the widest possible range. Not only do we recognise littoral and branchiate forms, but others achætous and leech-like in habit, to the extent of the discovery of a morphological overlap with the leeches, under which we are now compelled to remove them from their old association with the flat worms, and to unite them with the earthworms. And we even find these animals, as represented by the Acanthodrilidæ, coming prominently into considerations which involve the theory of a former Antarctic continent, one of the most revolutionary zoo-geographical topics of our time.

This case of the earthworm may be taken as typical of the rest, since for each and every class and order of animal forms, the progress of the period through which we have passed since last we assembled here has produced revolutionary results. Our knowledge of facts has become materially enhanced; our classifications, at best but the working expression of our ideas, have been to a large extent replaced in clearer, more comprehensive schemes; and we are to-day enabled to deduce, with an accuracy proportionate to our increased knowledge of fact, the nature of the interrelationships of the living forms which with ourselves inhabit the earth.

Satisfactory as is this result, it must be clearly borne in mind that its realisation could not have come about but for a knowledge of the animals of the past; and turning now to palæontology, it may be said that at the time of our last meeting in this city the scientific world was just becoming entranced by the promise of unexpected results in the exploration of the American Tertiary beds, then being first opened up. The Rocky Mountain district was the area under investigation, and with this, as with the progress in our knowledge of recent forms, no one living was prepared for the discoveries which shortly came to pass. To consider a concrete case, we may premise that study of the placental mammals had justified the conclusion that their ancestors must have had equal and pentadactyle limbs, a complete ulna and fibula, a complete clavicle, and a skull with forty-four teeth; must have realised, that is, the predominant term of the living Insectivora as generally understood. Who among the zoologists of our time does not recall with enthusiasm the revelation which arose from the discovery, during these early days, in the Eocene of Central North America, of the genera at first described as Eo- and Helohyus? The evidence of the existence, in the locality named, of these forty-four toothed peccaries, as they were held to be, rendered clearer the records of the later Tertiary deposits of the old world, which were those of hogs, and, in correlation with the facts then known, suggested that the Rocky Mountain area was the home of the ancestral porcine stock, and that in Early Tertiary times their descendants must have migrated, on the one hand, across the northern belt, of which the Aleutian Islands now mark the course, into the old world, to beget, by complication of their teeth, the pigs and hogs; and on the other into Central South America, to give rise, by numerical reduction of teeth and toes, to the peccaries, still extant.

Migration in opposite directions with diversity of modification was the refrain of this remarkable find, far-reaching in its morphological and zoo-geographical effects. Nor can we allude with less fervour to the still more striking case of the horses, which proved not merely a similar, though perhaps a later, migration, but a parallelism of modification in both the old and new worlds, culminating in the latter in extinction, whereby it became necessary, on the advent of civilised man, to carry back the old-world horse to its ancestral American home. No wonder that this should have provoked our Huxley to the remark that in it we have the "demonstrative evidence of the occurrence of evolution," and that the facts of palæontology came to be regarded as certainly not second to those of the fascinating but seductive department of embryology, at the time making giant strides.

I have endeavoured thus to picture that state of zoological science at the time of our last meeting here; and I wish now to confine myself to some of the broader results since achieved on the morphological side. But let us first digress, in order to be clear as to the meaning of this phrase.

We do not expect the public to be accurate in their usage of scientific terms; but it is to me an astounding fact that among trained scientific experts, devotees to branches of science other than our own, there exists a gross misunderstanding as to the

limitations of our departments. I quote from an official report in alluding to "comparative anatomists, or biologists, as they call themselves," and I but cite the words of an eminent scientific friend, in referring to biology and botany as coequal. In endeavouring to get rid of this prevailing error, let it be once more said that the term "biology" was introduced at the beginning of the nineteenth century by Treviranus and Lamarck, and that in its usage it has come to signify two totally distinct things as employed by our continental contemporaries and ourselves. By "Biologie" they understand the study of the organism in relation to its environment. We, following Huxley, include in our term biology the study of all phenomena manifested by living matter; botany and zoology; and by morphology we zoologists mean the study of structure in all its forms, of anatomy, histology and development, with palæontology—of all, that is, which can be preferably studied in the dead state, as distinct from physiology, the study of the living in action. Comparative morphology, the study of likeness and unlikeness, is the basis of our working classifications, and it is to the consideration of the morphological method, and the more salient of its recent results, that I would now proceed, in so far as it may be said to have marked progress and given precision to our ideas within the last eight-and-twenty years. I would deal in the main with facts, with theories only where self-evident, ignoring that type of generalisation to which the exclusive study of embryology has lent itself, which characterises, but does not grace, a vast portion of our recent zoological literature.

To the earnest student of zoology, intent on current advance, the mental image of the interrelationships of the greater groups of animal forms is ever changing, kaleidoscopically it may be, but with diminishing effect in proportion as our knowledge becomes the more precise.

Returning now to American palæontology, we may at once continue our theme. In this vast field, expedition after expedition has returned with material rich and plentiful; and while, by study of it, our knowledge of every living mammalian order, to say the least, has been extended, and in some cases revolutionised, we have come to regard the Early Tertiary period as the heyday of the mammals, in the sense that the present epoch is that of the smaller birds. No wonder then that there should have been discovered group after group which has become extinct, or evidence that in matters such as tooth-structure there is reason to believe that types identical with those of to-day have been previously evolved but to disappear. To contemplate the discovery of the Titanotheria, the Amblyopoda, the Dinocerata, with their strange diminutive brain, chief among the heavier ungulate forms, is to consider the Mammalia anew; and when it is found that among late discoveries we have (1) that of a series of Rhinoceratoidea, which though not yet known to extend so far back in time as the primitive tapirs and horses are complete as far as they go; (2) that among the Ruminants we have, in the Oreodontidæ of the American Eocene, primitive forms with a dentition of forty-four teeth, an absence of diastemata, a pentadactyle manus, a tetradactyle pes with traces of a hallux, and, as would appear from an example of Mesoreodon, a bony clavicle, such is unknown in any later ungulate, we are aroused to a pitch of eager enthusiasm as to the outcome of labours now in hand; for, as I write, there reaches me a letter to the effect that for most of the great vertebrate groups, and not the mammals alone, collections are still coming in, each more wonderful than the last.

In the extension of our knowledge of the Ancyclopoda, an order of mammals named after the Ancylotherium of Pikermi and Samos, which occur in the Early Tertiary deposits of Europe, Asia, North America and abundantly in Patagonia, we have been made aware of the existence of genera whose salient structural features combine the dentition of an ungulate with the possession of pointed claws, believed to have been retractile like those of the living cats. Conversely to these unguiculate herbivores, which include genera with limbs on both the artio- and perisso-dactyle lines, there have been found, among the so-called Mesonychidæ, undoubted primitive carnivores, indications of a type of terminal phalanx seal-like and approximately non-unguiculate; from all of which it is clear that we have in the rocks the remains of forms extinct which transpose the correlations of tooth and claw deducible from the living orders alone. Further, among the primitive pentadactyle Carnivora we meet, in the genus Patriofelis, with a reduction of the lower incisors to two, and characters of the fore-limb which, with this, suggest the seals. It is, however, probable that these characters are in no way indicative of direct genetic relationship between the two, for, inasmuch as these animals were accustomed to seek their food in the water of the lake by which they dwelt, their seal-like characters may be but the expression of adaptation to a partially aquatic mode of life—of parallelism of modification with the seals and nothing more.

Early in the history of their inquiry, our American confrères recorded from the Pliocene the discovery of camel-like forms possessed of a full upper incisor dentition; for example, the genera Protolabis and Ithygrammodon; and now they have arrived at the conclusion that while the camels are of American origin, one of their most characteristic ruminants, the Prongbuck (Antilocapra), would conversely appear to be the descendant of an ancestor (Blastomeryx) who migrated from the old world.

Sufficient this concerning the work in mammalogy of the American palæontologists. While we return them our devout and learned admiration, we would point out that the brilliance of their discoveries has but beclouded the recognition of equally important investigations going on elsewhere. In Argentina there have proceeded, side by side with the North American explorations, researches into the Pleistocene or Pampa fauna, which in result are not one whit behind, as has been proved by the recognition of a whole order of primitive ungulates, the Toxodontia, by that of toothed cetaceans with elongated nasals, as in the genera Prosqualodon and Argyrocetus, and of sperm whales with functional premaxillary teeth, viz. Physodon and Hypocetus, to say nothing of giant armadillos and pigmy glyptodons.

It will be remembered by some present that, from Patagonian deposits of supposed Cretaceous age, there was exhibited at our Dover meeting the skull of a horned chelonian Meiolania, which animal, we were informed, is barely distinguishable from the species originally discovered in Cook's Island, one of the Society group, and which, being a marsh turtle highly specialised, would seem in all probability to furnish a forcible defence for the theory of the Antarctic continent. But more than this, renewed investigation of the Argentine beds by the members of the Princeton University of North America have recently resulted in collections which, we are informed, seem likely to surpass all precedent in their bearings upon our current ideas, not the least remarkable preliminary announcement being the statement that there occurs fossil a mole indistinguishable, so far as is known, from the golden mole (Chrysochloris) of South Africa.

Before I dismiss this fascinating subject, let me disarm the notion, which may have arisen, that the palæontological work of the old world is done. Far from it! Even our American cousins have to come to us for important fossil forms; as, for example, the genus Pliohyrax of Samos and the Egyptian desert, while among the rodents and smaller carnivores there are large collections in our national museum waiting to be worked over afresh.

If one part of the globe more than another is just now the centre of interest concerning its vertebrate remains, it is the Egyptian desert. Here there have recently been found the bones of a huge cetacean associated, as in South America, with those of a giant snake, one of the longest known, since it must have reached a length of thirty feet. There also occur the remains of other snakes, of chelonians of remarkable adaptive type, of crocodilians, fishes and other animals. Interest, however, is greatest concerning the Mammalia, which for novelty are quite up to the American standard, as with an upper and a lower jaw of an anomalous creature, concerning which we can only at present remark that it may be a marsupial, or more probably a carnivore, which has taken on the rodent type in a manner peculiarly its own. Important beyond this, however, are a series of Eocene forms which more than fill a long-standing gap, viz., that of the ancestors of the Elephants and Mastodons, which hitherto stopped short in the Middle Miocene of both old and new worlds. As represented by the genus Mœritherium, they have three incisors above and two below, of which the second is in each case converted into a short but massive tusk. An upper canine is present, and in both upper and lower jaws a series of six cheek-teeth, distinct and bunodont in type. In the allied Barytherium, of which a large part of the skeleton is known, the upper incisors were presumably reduced to two, the tusks enlarged, with resemblances in detail to the Dinoceratan type.

So far as these remains are known, they appear to present in their combined characters all that the most ardent evolutionist

could desire. There are with them Mastodons which simplify our knowledge of this group; and among the last discovered remains Sirenians, which, in presenting a certain similarity to the afore-named Mæritherium, strengthen the belief in the proboscidian relationships of these aquatic forms. Finally, and perhaps most noticeable of all, there is the genus Arsinoitherium, a heavy brute with an olfactory vacuity which outrivals that of Grypotherium itself, and is surmounted by a monstrous fronto-nasal horn, swollen and bifid, for which the most formidable among the Titanotheres might yearn in vain. There is an occiput to match! The suggestion that this extraordinary beast has relationships with the Rhinoceridæ is absurd, since its tooth pattern alone inverts the order of this type. That it is a proboscidian may be nearer the mark, and if so it shows once more how subtle were the mammals of the past. Great as is this result, much remains to be done or done again, if only from the fact that in seeking to determine homologies our American brethren, in the opinion of some of us, have placed too much reliance on a so-called tritubercular theory of tooth genesis, of which we cannot admit the proof. How, we would ask, is it conceivable that a transversely ridged molar of Diprotodon type can be of tritubercular origin?

Sufficient for the moment of palæontological advance, except to remark that the zoologist who neglects this branch of morphology misses the one leavening influence; neglects the court on whose ruling arguments deduced from embryological data alone must either stand or fall. We may form our own conclusions from facts of the order before us; but it is when we find their influence on the master-mind prompting to action, like that of Huxley with his mighty memoir of 1880, in which he revised our subclass terms, that we appreciate them to the full.

With this consideration we pass to the living forms, and I have only time in dealing with these to comment on advance which affects our broadest conceptions and classifications of the past.

To commence with the Mammalia, we now know that the mammary gland when first it appears is in all forms tubular, and that this type is no longer distinctive of the Monotremata alone. We know, too, that the intranarial position of the epiglottis when at rest, long known for certain forms, is a distinction of the class. It explains the presence of the velum palatinum, by its association with the glottis for the restriction of the respiratory passage, the connection being lost in man alone, under specialisation of the organ of the voice.

Similarly, the doubly ossified condition of the coracoid may now be held diagnostic, for it is known that the epicoracoidal element, originally thought to characterise the monotremes alone, is always present, and that reduction to a varying degree characterises the metacoracoid, which retires, as in man, as the so-called coracoid epiphysis.

Our conceptions of the interrelationships of the Marsupialia and Placentalia have during the period we are considering been delimited beyond expectation, by the discovery of an allantoic placenta in a polyprotodont marsupial, in place of the vitelline, present in its allies. When it is remembered that in the formation of the placenta of the rabbit and a bat there is realised a provisional vitelline stage, it is tempting to suggest that the evidence for the direct relationship of the two mammalian subclasses first named overlaps (there being a placental marsupial on the one hand, a marsupial placental on the other), much as we have come to regard Archæopteryx as an avian reptile, the Odontornithes as reptilian birds. These facts, moreover, prove that the type of placenta inherited by the Placentalia must have been discoidal, and that from that all others were derived.

Equally important concerning our knowledge of the Marsupialia is the discovery, first made clear by Prof. Symington, of this College, that Owen was correct in denying them a corpus callosum. How Owen arrived at this conclusion it is difficult to conceive; but in these later days the history of discovery is largely that of method; and it is by the employment of chrome-silver, methylene-blue, and other reagents, which in differentiating the fibre-tracts enable us to delimit their course, that this conclusion has been proved. By the corpus callosum we now understand a series of neo-pallial fibres which transect the alveus and are present only in the Placentalia.

There is no department of mammalogy in which recent work has been more luminous than this which concerns the brain; and, to mention but one result, it may be said that in the renewed study of the commissures there has been found a fibre-tract characteristic of the Diprotodontia alone, so situated as to prove that they and the Placentalia must have specialised on diverse lines from a polyprotodont stock. Interesting this, the more, since the phalangers and kangaroos are known to be polyprotodont when young. And when we add the discovery that in the detailed relationship of its commissures the brain of the Elephant Shrew, a lowly insectivore, alone among that of all Placentalia known, realises the marsupial state, as does its accessory organ of smell, we have to admit the discovery of annectant conditions just where they should occur.

The morphological method is sound!

The master hand which has given us this result has also reinvestigated the Lemurs. From an exhaustive study of the brain or its cast of all species of the order, living and extinct, there has come the proof that the distinctive characters of the lemuroid brain are intelligible only on a knowledge of the pithecoid type; that its structural simplicity in the so-called lower lemurs is due to retrogressive change, in some species proved to be ontogenetic; and that the Tarsier, recently claimed to be an insectivore, is a lemur of lemurs. It is impossible to over-estimate the importance of this conclusion, which receives confirmation in recent palæontological work; and there is demanded a reinvestigation of those early described Tertiary fossil forms placed on the Ungulo-lemuroid border line, as also a reconsideration of current views on the evolution of the primates and of man.

In dismissing the Mammalia, we recall the capture during the period we review of three new genera, a fourth, the so-called Neomylodon, having proved by its skull to be *Grypotherium Darwinii*, already known. The African Okapi, an object of sensation beyonds its deserts, has found its place at last. To have been dubbed a donkey, a zebra and a primitive hornless giraffe is distinction indeed; and we cannot refrain from contrasting the nonsensical statement that its discovery is "the most important since Archæopteryx" with the truth that it is a giraffine, horned for both sexes, annectant between two groups well known. As a discovery it does not compare with that of the Mole-marsupial, and it falls into insignificance beside that of the South American diprotodont Cœnolestes, the survivor of a family which there flourished in Middle Tertiary times.

Passing to Birds and Reptiles, it will be convenient to consider them together. A knowledge of their anatomy has extended on all hands, and in respect to nothing more instructively than their organs of respiration. Surprise must be expressed at the discovery, in the chelonian, of a mode of advancing complication of the lung suggestive of that of birds. On looking into this, I find that Huxley, who rationalised our knowledge of the avian lung and its sacs, was aware of the fact that in our common Water-tortoise (*Emys orbicularis*), the lung is sharply differentiated along the bronchial line into a postero-dorsal more cellular mass, an antero-ventral more saccular, of which the posterior vesicle, in its extension and bronchial relationships, strangely simulates the so called abdominal sac of birds. He had already instituted comparison with the Crocodiles, aud was clearly coming to the conclusion that the arrangement in the bird is but the result of extreme specialisation of a type common to all Sauropsida with a "cellular" lung. The respiratory process in the bird may be defined as transpulmonary, and it is an interesting coincidence that, as I write, there comes to hand a memoir, supporting Huxley's conclusion, and establishing the fact that there is a fundamental principle underlying the development and primary differentiation of all types of vertebrate lung.

The discovery of the Odontornithes in the American Cretaceous is so well known, that it is but necessary to remark that nine genera and some twenty species are recognised. To Archæopteryx I shall return. Before dismissing the Chelonia, however, it must be pointed out that palæontology has definitely clenched their supposed relationship to the Plesiosaurs. Of all recent palæontological collections there are none which, for care in collecting and skill in mounting, surpass the reptilian remains from the English Jurassic (Oxford Clay) now public in our national museum. The Plesiosaurs of this series must be seen to be appreciated, and nothing short of a merciful Providence can have interposed, to ensure the generic name Cryptocleidus, which one of them has received, since the hiding of the clavicle, its diagnostic character, is an accomplished fact. It is due to secondary displacement, under the approximation in the middle line of a pair of proscapular lobes, present in the Plesiosauria and Chelonia alone, and until the advent of this discovery mis-

interpreted. Taken in conjunction with other characters of little less importance, conspicuously those of the plastron and pelvis, this decides the question of affinity, and proves the Chelonia to have had a lowly ancestry, as has generally been maintained.
